Triethylene Glycol Derivatives. Monomethyl ether: Dowanol TM Glycol Ether.

9. Uses

Ethylene glycol lowers the freezing point of water (see Fig. 1). Its ease of handling makes it a perfect antifreeze [51], which accounts for over 50 % of its commercial uses (→ Antifreezes).

Commercial antifreezes based on glycol also contain corrosion inhibitors and are used, for example, in motor vehicles, solar energy units, heat pumps, water heating systems, and industrial cooling systems. Protection against freezing is directly related to the glycol concentration; 60 % glycol prevents freezing down to a temperature of −55 °C. There is little point using higher concentrations because the freezing point then starts to increase (Fig. 1).

Ethylene glycol is also a commercially important raw material for the manufacture of polyester fibers, chiefly poly(ethylene terephthalate) (→ Fibers, 4. Synthetic Organic). This application consumes ca. 40 % of the total ethylene glycol production. Polyesters are, however, used for other purposes, e.g., for producing recyclable bottles (→ Polyesters). Other minor uses of ethylene glycol are as a humectant (moisture-retaining agent), plasticizer, softener, hydraulic fluid, and solvent [52].

Ethylene glycol derivatives, mainly the ethers and esters, are frequently employed as reaction media, as absorption fluids, and as solvents for dyes, lacquers, and various cellulose products (cellulose esters, ethers, and nitrocellulose) [53].

Diethylene glycol serves as a solvent, softener (cork, adhesives, paper, etc.), dye additive (printing and stamping inks), deicing agent for runways and aircraft [54], and a drying agent for gases (e.g., natural gas) [55].

Triethylene glycol is used for the same purposes as diethylene glycol (e.g., as a solvent, plasticizer, and drying agent for gases) [56].

Poly(ethylene glycols) with varying molecular masses find numerous uses in the pharmaceutical industry (e.g., in ointments, liquids, and tabletting) and the cosmetic industry (e.g., creams, lotions, pastes, cosmetic sticks, and soaps). They are also used in the textile industry (e.g., cleaning and dyeing aids), in the rubber industry (e.g., lubricants and mold parting agents), and in ceramics (e.g., bonding agents and plasticizers) [57].

10. Economic Aspects

Ethylene glycol is one of the major products of the chemical industry. Its economic importance is founded on its two major commercial uses – as an antifreeze and for fiber production. Since ethylene glycol is currently produced exclusively from ethylene oxide (→ Ethylene Oxide), production plants are always located close to plants that produce ethylene oxide. The proportion of ethylene oxide that is converted to glycol depends on the local conditions, such as transport facilities and the market situation. Almost all of the ethylene oxide produced in recently installed plants in Saudi Arabia is, for example, converted to ethylene glycol because the domestic market for ethylene oxide is negligible and because ethylene glycol is easier to transport than ethylene oxide.

Detailed information about the glycol capacities of individual plants is difficult to obtain, but an estimated 60 % of the total world production of ethylene oxide is converted to ethylene glycol. Therefore, the worldwide ethylene oxide production capacity of 8×10^6 t corresponds to an annual ethylene glycol production of 6.7×10^6 t.

About 50 % of the ethylene glycol that is produced is used in antifreeze. Another 40 % is channeled into the fiber industry. Consequently, the ethylene glycol demand is closely connected to the development of these two sectors. Surplus capacities and growing competition for market shares are expected on account of increasing glycol capacities – not only in Saudi Arabia, but also in the Eastern Bloc. Japan has already reduced its glycol capacities considerably [58]. In view of the increasing price of crude oil, alternative production methods based on synthesis gas – hitherto still in the experimental phase – are likely to become more important and increasingly competitive.

11. Toxicology and Occupational Health

11.1. Ethylene Glycol

Oral Toxicity. The oral LD_{50} values of ethylene glycol are 14 – 15 g/kg [59], [60] for mice and ca. 8 g/kg [61] for rats. Oral toxicity in humans is higher, 1.4 g/kg can be lethal [59].

In rats, long-term administration of ethylene glycol in food at concentrations of 10.0 and 20.0 g/kg led to formation of bladder stones (calcium oxalate), damage to the renal tubules, and centrolobular fatty degeneration of the liver [62]. In other investigations, comparable changes were already apparent at a concentration of 5.0 g/kg, no changes were observed at 2.0 g/kg [63]. No changes were observed in the kidneys of monkeys fed a diet providing a maximal daily dose of 0.17 g/kg of body mass over a period of three years [64]. However, addition of ethylene glycol to the drinking water given to monkeys at a concentration corresponding to a daily dose of 0.24 g/kg of body mass led to the formation of oxalate crystals in the kidneys after about five months. Oxalate crystals were also formed in the brains of monkeys given very high doses (10 wt %) in drinking water [65].

Eye and Skin Irritation. Introduction of a single dose of ethylene glycol into the conjunctival sac does not affect the rabbit eye [66], but repeated administration leads to mild conjunctivitis [67]. Ethylene glycol vapor at a concentration of 17 mg/m^3 produces ocular damage in humans [68]. No effects were observed in the eyes of monkeys exposed to a vapor concentration of 265 mg/m^3 [68].

Ethylene glycol has not been shown to irritate mucous membranes. Repeated exposure of the skin to ethylene glycol can cause mild irritation, similar to that produced by glycerol.

Inhalation. The inhalative toxicity of an atmosphere saturated with ethylene glycol (0.5 mg/L) is low. Rats tolerated this concentration for four weeks without any permanent injuries, only mild narcosis was observed [69].

No adverse effects were detected in rats, rabbits, guinea pigs, dogs, and monkeys exposed to an ethylene glycol concentration of 57 mg/L for six weeks [70]. Monkeys survived after inhaling concentrations of 600 mg/m^3 administered as an aerosol over a period of several months.

Human volunteers exposed to maximal concentrations of 67 mg/m^3 for one month reported some irritation of the nasal mucous membranes and occasionally headache. The presence of ethylene glycol in the inhaled atmosphere was perceived at concentrations above 140 mg/m^3 [71]. A concentration of 200 mg/m^3 was found to be intolerable [72]. Rats, rabbits, dogs, and monkeys that inhaled pure oxygen containing 100 mL/m^3 of ethylene glycol at a pressure of 34.5 kPa for three weeks did not show any adverse effects apart from local irritation [73].

Mutagenicity and Carcinogenicity. Ethylene glycol gives a negative result in the Ames test [74], [75]. Many studies have been performed on its carcinogenicity [64], [76], [77]. Rats were fed with diets containing ethylene glycol concentrations corresponding to 1000, 200, and 40 mg/kg of body mass; no carcinogenic effects were observed. However, typical formation of oxalate crystals in the kidneys and other organs was found [78]. Similar experiments did not increase the incidence of tumor formation in mice [79].

Reproduction. In a study extending over three generations, ethylene glycol was added to the diet fed to rats at a concentration of 0.04, 0.2, and 1.0 g kg^{-1} d^{-1}. The fertility and viability of the offspring were not affected by this treatment [80].

Teratogenic effects were not detected in rats receiving maximal feed concentrations of 1000 mg/kg, only a mild fetal toxicity was observed [81]. Teratogenic and fetotoxic effects were produced in mice and rats after administration of very high doses (1.25, 2.50, and 5.00 g/kg of body mass) in the form of a bolus with the aid of an esophageal probe [82].

Metabolism. In the body, ethylene glycol is degraded by alcohol dehydrogenase to form glycolaldehyde, which is further degraded by an aldehyde oxidase to produce glyoxal. Glyoxal is subsequently metabolized to glycolic and glyoxylic acids, from which oxalic acid, formic acid, glycine, 2-oxo-4-hydroxygluconate, 2-hydroxy-3-oxoadipate and oxomalate are formed [83, p. 3827].

11.2. Ethylene Glycol Derivatives

Toxicity data and exposure limits for ethylene glycols and some monoethylene glycol derivatives are listed in Table 8.

Diethylene glycol has a low acute oral toxicity (see Table 8). A LDLo value of 1.0 mL/kg is often erroneously cited but this value was determined using a preparation that contained sulfanilimide [85].

In long-term studies performed over a period of two years, dietary levels of 1, 2, and 4 % diethylene glycol administered to rats produced calcium oxalate stones with associated kidney and liver damage [86]. Chronic mechanical irritation of the bladder epithelium by the resulting bladder stones led to the formation of benign tumors. Production of calcium oxalate stones is attributed to contamination of the diethylene glycol with monoethylene glycol (see Section 11.1) [87], [88]. The low cumulative toxicity of diethylene glycol has been confirmed [89–91].

Diethylene glycol does not irritate the eyes or skin [92]; absorption by the skin is extremely low [93]. Diethylene glycol does not affect the fertility of rats [94]. It does not display mutagenicity in the Ames test [95]; other studies also suggest that the compound is not carcinogenic [87], [88].

Triethylene glycol has an extremely low oral toxicity when given either in a single dose (see Table 8) or in repeated doses [86], [96]. This compound causes only slight irritation of the skin and mucous membranes, it is not teratogenic [97].

Table 8. Toxicity data and exposure limits for ethylene glycols and ethylene glycol derivatives

Compound	Single oral LD_{50} in rats, g/kg	Reference	MAK, ppm	TLV-TWA, ppm
Ethylene glycols				
Monoethylene glycol	8	[61]	10	50
Diethylene glycol	20.8	[61]	10	
Triethylene glycol	22.1	[61]		
Tetraethylene glycol	30.8 *	[83, p. 3843]		
Monoethylene glycol derivatives				
Monomethyl ether (methoxyethanol)	3.4	[84]	5	5
Monomethyl ether acetate (methoxyethyl acetate)	3.93	[61]	5	5
Monoethyl ether (ethoxyethanol)	5.5	[84]	5	5
Monoethyl ether acetate (ethoxyethyl acetate)	5.1	[61]	5	5
Monobutyl ether (butoxyethanol)	2.5	[84]	20	25
Monobutyl ether acetate (butoxyethyl acetate)			20	

* mL/kg

Tetraethylene glycol is, like triethylene glycol, nontoxic (see Table 8).

Poly(ethylene glycols) have an extremely low acute oral toxicity (LD_{50} in rats > 30 g/kg) which decreases as their molecular mass increases [98]. Studies on rats [98] and dogs [99] have shown that their cumulative toxicity is also very low.

Irritation of the skin and mucous membranes in humans and animals is slight. When applied to the skin, pure poly(ethylene glycols) do not cause sensitization [98], [100], [101] and are nontoxic [98]. Poly(ethylene glycols) with a molecular mass < 1000 are absorbed in the intestine and excreted in the urine and feces. Intestinal absorption decreases markedly as the molecular mass increases [102–104].

1. Introduction

Ethylene oxide (oxirane) [*75-21-8*], M_r 44.05, is the simplest cyclic ether. It is a colorless gas or liquid and has a sweet, etheric odor. The ethylene oxide molecule with its short C–C bond and strained angles is shown in Figure 1 [6]. Theoretical calculations of the structure are in good agreement with experimental results [7].

Figure 1. The ethylene oxide molecule

Ethylene oxide is very reactive because its highly strained ring can be opened easily, and is thus one of the most versatile chemical intermediates. Because of its reactivity and toxicity it is also a hazardous compound that has been involved in a number of serious incidents. A good understanding of its properties is a necessary prerequisite for its safe handling. Ethylene oxide was first described in 1859 by WURTZ [8], who prepared it by eliminating hydrochloric acid from ethylenechlorohydrin, using potassium hydroxide solution. Industrial production by the chlorohydrin process began in 1914 and was based on WURTZ's discovery. Since then the production and importance of ethylene oxide have steadily grown.

In 1931, LEFORT [9] discovered the direct catalytic oxidation of ethylene [*74-85-1*], which gradually superseded the chlorohydrin process. Currently, ethylene oxide is produced by direct oxidation of ethylene with air or oxygen; annual worldwide production capacity is ca. 15×10^6 t, making it an important industrial chemical. Ethylene oxide itself is used as a disinfectant, sterilizing agent, and fumigant. Its most important derivative is ethylene glycol [*107-21-1*], which is used in antifreeze (car radiators) (→ Antifreezes) and for the manufacture of polyester fibers (→ Fibers, 4. Synthetic Organic; → Polyesters). Other ethylene oxide derivatives, amines and poly(ethylene glycols), are used in surfactants, solvents, etc.

There is some endogenous formation from ethylene in humans [10], and it has been discovered in an interstellar source [11].

As atmospheric pollutant it is present in natural gas, cigarette smoke, and diesel exhaust.

Though ethylene oxide in nature is rare its biological action may have a fundamental impact on DNA and RNA evolution of whole biological systems [12].

2. Physical Properties

Some physical properties of ethylene oxide are summarized in Table 1.

Table 1. Physical properties of ethylene oxide [5], [13], [14]

mp at 101.3 kPa	−112.5 °C
bp at 101.3 kPa	10.8 °C
Critical temperature	195.8 °C
Critical pressure	7.2 MPa
Critical density	314 kg/m^3
Refractive index, n_D^7	1.3597
Explosive limits in air at 101.3 kPa	
lower	2.6 vol %
upper	100.0 vol %
Electrical conductivity	4×10^{-6} S/m
Dielectric constant	
at −1 °C (liquid)	13.9
at 15 °C (vapor)	1.01
Heat of combustion at 25 °C, 101.3 kPa	29.648 kJ/kg
Entropy of the vapor at 101.3 kPa	
10.5 °C	5.439 kJ kg^{-1} K^{-1}
25.0 °C	5.495 kJ kg^{-1} K^{-1}
Ignition temperature in air at 101.3 kPa	429 °C
Ignition energy in air at 101.3 kPa and 25 °C	0.087 mJ
Minimum ignition energy of the gas at 220 kPa and 100 °C	64 mJ
Decomposition temperature of the vapor at 101.3 kPa	571 °C
Heat of polymerization	2091 kJ/kg
Heat of fusion	117.86 kJ/kg
Heat of decomposition of the vapor	1901 kJ/kg
Coefficient of cubic expansion	
at 22 °C	0.00161
at 55 °C	0.00170
Heat of solution in water at 25 °C	142.57 kJ/kg

In the pressure range 0 – 101.3 kPa and at 40 and 60 °C, the solubility of ethylene oxide in water obeys Henry's law. The Henry constants for these temperatures are 2.875 and 1.448, respectively. However, at 20 °C a more than proportional increase in solubility occurs with the partial pressure [15].

Liquid ethylene oxide and water are completely miscible in all proportions. Table 2 shows some of the properties of aqueous ethylene oxide solutions. Of particular note are the relatively high melting points, which are due to clathrate formation [17]. Clathrates consist of organic molecules that are enclosed in a cage structure. In this case, the cage is an ice lattice which is composed of unit cells, each containing 46 water molecules, and two types of cavities: six larger ones (14-sided, tetradecahedra) and two smaller ones (12-sided, dodecahedra). If the clathrates are made to crystallize from increasingly concentrated aqueous solutions of ethylene oxide, their density and ethylene oxide content also increase. Ethylene oxide first fills the six tetradecahedral cavities of the water lattice, followed by 20 – 40 % of the dodecahedral cavities [18].

The temperatures for the formation of ice and hydrate from mixtures of ethylene oxide and water for concentrations of 0 to 97.89 wt % ethylene oxide gave a highest hydrate formation temperature of 11.08 °C at an ethylene oxide concentration of 26.15 wt %. The hydrate corresponds to a composition of 6.91 molecules of water per molecule ethylene oxide. The unit cell consists of 46 water molecules and 6.66 ethylene oxide molecules. The eutectic point of the mixture has been determined to lie at 2.107 °C and 4.75 wt % ethylene oxide (Fig. 2) [19].

Figure 2. Hydrate-formation temperature as a function of ethylene oxide concentration

There are also mixed clathrates, in which the small cages are occupied by ethylene oxide and the big cages by molecules with an higher space requirement, e.g., tetrahydrofuran [20].

Table 2. Physical properties of aqueous ethylene oxide solutions [3], [5], [16]

Ethylene oxide content, wt %	*mp*, °C	*bp*, °C	Density at 10 °C, g/L	Flash point, °C

80	3.7	13	0.9194	−53
100	−112.5	10.4	0.8826	−57

The solubilities of gases in ethylene oxide vary, increasing in the order nitrogen, argon, methane, ethane. Earlier data [21] have been revised [22]. The Henry constants for these gases in ethylene oxide at different temperatures are given in Table 3.

Table 4 shows other temperature-dependent physical properties of gaseous and liquid ethylene oxide.

3. Chemical Properties

Ethylene oxide is a very reactive, versatile compound. Its reactions proceed mainly via ring opening and are highly exothermic. Explosive decomposition of the ethylene oxide vapor may occur at higher temperatures if heat dissipation is inadequate. Only the most important types of the large number of possible reactions are briefly discussed here. More detailed information can be found in [25–29].

Decomposition. Gaseous ethylene oxide starts to decompose at ca. 400 °C to form mainly CO, CH_4, as well as C_2H_6, C_2H_4, H_2, C, and CH_3CHO. The first step in the decomposition is presumed to be the isomerization of ethylene oxide to acetaldehyde [30]. Once the decomposition reaction has been initiated (ignition source), it can be propagated through the gas phase and, under certain conditions, may be explosive (see Chap. 8).

Addition to Compounds with a Labile Hydrogen Atom. Ethylene oxide reacts with compounds containing a labile hydrogen atom to form a product containing a hydroxyethyl group:

Examples of XH are: HOH, H_2NH, HRNH, R_2NH, RCOOH, $RCONH_2$, HSH, RSH, ROH, N≡CH, and B_2H_6 (R = alkyl, aryl). The reaction is accelerated by acids and bases. During acid catalysis, the ethylene oxide is first protonated to form an epoxonium ion (**1**), which is in equilibrium with the corresponding hydroxycarbenium ion (**2**). The anion X^- can then react with **1** or **2** in an S_N2 or S_N1 reaction, respectively. In an alkaline medium, the S_N2 mechanism is favored. A detailed discussion of reaction mechanisms can be found in [27], [31].

1 **2**

The protonation of ethylene oxide by various H-active compounds in tetrachloromethane can be detected by IR spectroscopy. Broadening and shift of the IR bands in the region of 530 to 740 cm^{-1} depend on the type of H-active compound (OH, NH, CH) [32]. Analogous protonated intermediates have been postulated in gas-phase S_N2 reactions of ethylene oxide on the basis of theoretical and experimental results [33].

Table 3. Solubility of gases in ethylene oxide (Henry constants in MPa) [22], [23]

Temperature, °C	Solubility in ethylene oxide			
	Nitrogen	Argon	Methane	Ethane

All common acids and Lewis acids as well as zeolites, ion exchangers [34], and aluminum oxide are effective catalysts. Solid polymeric acids (cation exchangers) are especially recommended for the reaction of ethylene oxide with methanol [35].

As the end product of the above reaction contains at least one hydroxyl group, it may react successively with further ethylene oxide molecules:

The molecular mass of the resulting polymers depends on the ratio of the reactants, the catalyst used, and the reaction conditions [1], [28].

A byproduct of the acid-catalyzed polymerization is dioxane, which may even be the sole product with a large excess of ethylene oxide. An explanation for this behavior is offered by the assumption that two different reaction mechanisms are effective. The first is the active chain end (ACE) mechanism, which leads to dioxane and poly(ethylene glycol).

And the second is the activated monomer (AM) mechanism, which leads exclusively to poly(ethylene glycol).

One of the conditions which favor the ACM mechanism and therefore the formation of dioxane is an increasing excess of ethylene oxide [36].

A large variety of reactions occur between ethylene oxide and compounds containing labile hydrogen atoms; therefore, such compounds are often used to produce derivatives.

Commercially, the most important of this type of reaction is the hydrolysis of ethylene oxide to ethylene glycol. About 60 % of the total ethylene oxide production is converted into ethylene glycol in this way (→ Ethylene Glycol). However, this reaction, which is often referred to as ethoxylation, is also used to produce the bulk of all the other commercially important ethylene oxide derivatives. The ethoxylation products of alkyl phenols, ammonia, fatty alcohols, fatty amines, and fatty acids have a variety of uses [28]. Although polymer formation according to the above equation is more likely to be an unwanted side reaction, the production of poly(ethylene glycols) of widely varying molecular mass by this route is of some importance [37]. Undesired polymerization may be catalyzed by rust in rusty containers [38].

Reaction with Water. The formation of hydrates is discussed in Chapter 2. Hydrolysis is the most important reaction of ethylene oxide: about 60% of the total ethylene oxide production is transformed into ethylene glycol. The reaction of ethylene oxide with water in the absence of catalysts at 20 °C is relatively slow, as shown by the half-life of 20 d. The dependence of the half-life of a 3 % solution of ethylene oxide in water on pH is shown in Figure 3. The dependence is characterized by a bell-shaped curve with a relatively broad plateau from pH 5 to 11 and a steep slope on both sides. A strong acceleration occurs only below pH 4 and above pH 12. Byproducts of the hydrolysis are diethylene glycol, triethylene glycol, and higher molecular mass poly(ethylene glycols). The percentage of ethylene oxide converted to these products depends almost solely on the ratio of water to ethylene oxide in the starting material and only marginally on pH and temperature.

Figure 3. Half-life of 3 wt % ethylene oxide in water as a function of pH at 8 and 20 °C

Reaction with DNA, RNA and Proteins. The major product of reaction with DNA is 7-(2-hydroxyethyl) guanine. Further reaction products are (2-hydroxyethyl) guanine and 3-(2-hydroxyethyl) adenine [12].

In men exposed to ethylene oxide, adducts with hemoglobin can be found and its level may be evaluated by the concentration of (2-hydroxyethyl) valine [39].

Addition to Double Bonds. Ethylene oxide can add to compounds with double bonds, e.g., carbon dioxide [40], to form cyclic products:

Ethylene carbonate
(1,3-dioxolan-2-one)

Quaternary ammonium compounds are suitable catalysts for this reaction, which then proceeds at 200 °C and 8 MPa [41]. Use of porphine complexes of aluminum in solvents such as chloroform allows the reaction to take place at nor-

mal pressure and at room temperature [42]. Hydrolysis of ethylene carbonate (1,3-dioxolan-2-one) [*96-49-1*] yields pure ethylene glycol [43]. Therefore, the reaction is of interest for the selective production of ethylene glycol from ethylene oxide, i.e., for avoiding the partly unwanted formation of poly(ethylene glycols) [44].

Ethylene oxide also adds to other double bond systems, e.g., to $R_2C{=}O$ [45], SC=S, $O_2S{=}O$, RN=CO, and OS=O.

Catalytic Isomerization to Acetaldehyde. Aluminum oxide (Al_2O_3) [46], phosphoric acid and phosphates [47], and under certain conditions silver [48] catalyze the isomerization of ethylene oxide to acetaldehyde.

Reduction to Ethanol. Reduction of ethylene oxide to ethanol is catalyzed by Ni, Cu, and Cr on Al_2O_3 [49].

Reaction with Grignard Reagents. Grignard reagents react with ethylene oxide to produce compounds with a primary hydroxyl group [29], [50].

Reaction with Lithium Acetylide. Acetylene is treated with lithium in liquid ammonia to form the lithium salt, which reacts with ethylene oxide at −33 °C to give 3-butyne-1-ol in 80 % yield [51].

Reaction with Synthesis Gas. Ethylene oxide is carbonylated with CO/H_2 in the presence of rhodium catalysts in tetraethylene glycol dimethyl ether to give 1,3-propanediol in good yields [52].

Oligomerization to Crown Ethers. Ethylene oxide oligomerizes to form cyclic polyethers (crown ethers) in the presence of a fluorinated Lewis acid catalyst (→ Crown Ethers).

Synthesis is successful when groups that saturate potential terminal hydroxyl groups are absent [53]. Suitable catalysts are the BF_4^-, PF_6^-, or SbF_6^- salts of metal cations. The reaction can be directed to produce a particular oligomer by choosing an appropriate metal cation. The size of the cation determines the size of the crown ether ring by acting as a template [54]. For example, with $CsBF_4$, only the cyclic hexamer ($n = 3$), 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6) [*17455-13-9*], is produced; if $Cu(BF_4)_2$ is used, 90 % of the product consists of the pentamer ($n = 2$), 1,4,7,10,13-pentaoxacyclopentadecane (15-crown-6) [*33100-27-5*], and with $Ca(BF_4)_2$, a mixture of the tetramer (50 %, $n = 1$), 1,4,7,10-tetraoxacyclodecane (12-crown-4) [*294-93-9*], and the pentamer, 1,4,7,10,13-pentaoxacyclopentadecane (18-crown-6) [*17455-13-9*], is produced.

Reaction with Dimethyl Ether. Ethylene oxide reacts with dimethyl ether to produce poly(ethylene glycol) dimethyl ethers (→ Dimethyl Ether); this reaction is used for the industrial production of the lower molecular mass homologues, which are widely used as solvents [55].

Reaction with Bromotrimethylsilane. Ethylene oxide adds to bromotrimethylsilane [*2857-97-8*] in a highly exothermic reaction with excellent yields [56].

Disproportionation in the presence of iron oxides (especially γ-Fe_2O_3 and γ-FeOOH) has been described as the cause of an explosion (see Chap. 8) [57].

$$4\,C_2H_4O \longrightarrow 3\,C_2H_4 + 2\,CO_2 + 2\,H_2$$

$$5\,C_2H_4O \longrightarrow 4\,C_2H_4 + 2\,CO_2 + H_2 + H_2O$$

$$6\,C_2H_4O \longrightarrow 5\,C_2H_4 + 2\,CO_2 + 2\,H_2O$$

4. Production

As mentioned in the introduction, ethylene oxide was produced formerly by the chlorohydrin process (→ Chlorohydrins, Chap. 4.). However, this method is no longer used on an industrial scale; a description is given in [58]. Although the selectivity of this process (80 %) was satisfactory, practically all of the chlorine that was used was lost as calcium chloride and unwanted chlorine-containing byproducts were generated. This not only was inefficient, but also caused pollution problems so that this method has now been replaced by the direct oxidation process.

WURTZ, who had discovered ethylene oxide, attempted as early as 1863 to produce it by direct oxidation of ethylene with oxygen, but did not succeed [59]. Many other unsuccessful attempts were made [60] before LEFORT made the crucial discovery in 1931 that the formation of ethylene oxide from ethylene and oxygen was catalyzed by metallic silver [9]. Since the catalyst plays a central role in the production process, it is discussed first.

4.1. Catalysts

To date no other metal has been found that can compete with silver in the catalysis of the direct oxidation of ethylene to ethylene oxide. However, the silver catalysts have been substantially improved since their discovery by LEFORT [9].

Figure 4. Silver catalyst for ethylene oxide production (SEM, × 10 000)

Only supported catalysts are used, the silver being deposited on a porous *support material* in concentrations of 7 – 20 %. The support material is of critical importance [61]; currently, preference is given to ultrapure (over 99 %) aluminum oxide [*57828-03-2*] fired at a high temperature that has a defined pore structure (pore diameter 0.5 – 50 µm) and low specific surface area (<2 m^2/g). Although supports with higher specific surface areas are very active, their selectivity is low, presumably because ethylene oxide can diffuse only slowly out of the smaller pores and, therefore, can be further oxidized [62]. Supports with chemical activity towards ethylene or ethylene oxide are unsuitable. All support containing hydroxyl groups catalyze the isomerization of ethylene oxide to acetaldehyde. As total oxidation of acetaldehyde is very fast on silver, catalysts consisting of silver and carriers like γ-alumina, SiO_2, MgO, SiC, TiO_2, Y_2O_3, and ZrO_2 give only poor selectivities or form only CO_2 and H_2O [63]. Silane treatment of supports

containing hydroxyl groups improves the performance in ethylene oxide formation, and this confirms the detrimental effect of hydroxyl groups, which result in isomerization of ethylene oxide to acetaldehyde [64].

The impregnation methods used to deposit the silver on the support are being constantly improved. Complexes of silver salts with amino compounds are used which decompose to give evenly and finely distributed silver particles with a diameter of 0.1 – 1 µm [65]. Figure 4 shows a scanning electron micrograph (SEM) of the inner surface of a silver catalyst particle.

In addition, 100 – 500 mg/kg of *promoters* such as salts or other compounds of alkali and alkaline earth metals are added to the catalyst, significantly improving the selectivity. Among the alkali metal salts, those of cesium are especially effective [66]. Promoters are often combined. An especially effective combination consists of rhenium, sulfur, tungsten, molybdenum and results in outstanding selectivities of up to 90 %, albeit at higher temperature and reduced catalyst life [67].

Addition of chlorine compounds to the reaction gases improves selectivity [68]. These *inhibitors* (e.g., 1,2-dichloroethane, vinyl chloride [69], ethyl chloride) [70] suppress the combustion of ethylene to carbon dioxide and water; they ensure that the silver surface is covered evenly with a supply of chlorine [71].

The advances made in silver-based catalysts since LEFORT's original discovery (i.e., optimized support materials, silver distribution, and use of promoters and inhibitors) have improved selectivity from 50 to about 90 %. Silver has maintained its position as the only known metal that can catalyze the oxidation of ethylene to ethylene oxide with a commercially viable selectivity.

The silver catalysts used in ethylene oxide production are not suited for the production of epoxides from olefins with allylic hydrogen atoms (e.g., propene); total oxidation is the prevailing reaction. Nonallylic olefins such as butadiene are reported to form epoxides in reasonable yields [72].

Aging of the Catalyst. Modern silver-based catalysts have an initial selectivity of 80 – 90 %; a maximum selectivity of 90 % is commercially feasible [44]. The disadvantages associated with highly selective catalysts are that they age relatively quickly and less heat is produced. As the catalyst is used, its selectivity and activity gradually deteriorate [73–75] due to

1) Abrasion, dust formation, and blocking of pores.
2) Accumulation of detrimental impurities introduced with the reaction gases (e.g., sulfur from ethylene or methane).
3) Changes in the silver particles, which enlarge, form agglomerates, and become unevenly distributed. Thus, the installed silver surface, which is about 20 km^2 for 100 t/a ethylene oxide capacity, drops to about 50 % of its initial value by sintering during two years on stream. To compensate this reduction in silver surface the reaction temperature (reaction velocity) has to be increased accordingly to maintain the production rate.

Generally applicable methods of regenerating such catalysts are unknown; the only method of any importance is the use of methanolic solutions of cesium salts [76]. If regeneration is impossible, it becomes economically necessary to replace the catalyst when selectivity has fallen to a critical level or becomes technically necessary because the reaction temperature has reached the maximum design value. The lifetime of a modern catalyst is two to five years, depending on the type of catalyst (high-selectivity catalysts have considerably shorter life times), the rate of ethylene oxide production, and the purity of the reaction gases (sulfur is extremely poisonous). From the spent catalysts silver is recovered in high purity and with only small losses, while the used supports are waste.

4.2. Mechanism of Catalysis

Two reactions take place simultaneously at the silver surface. In addition to ethylene oxide formation (partial oxidation, Eq. 1), complete combustion (total oxidation, Eq. 2) to CO_2 and water also takes place. Small amounts of acetaldehyde and formaldehyde are also formed [77]. The reactions given by Equations (1) and (2) are exothermic, their enthalpies being −106.7 and −1323 kJ/mol, respectively at 250 °C and 1.5 MPa [44].

$$H_2C{=}CH_2 + \tfrac{1}{2}\,O_2 \longrightarrow \triangledown_{O}$$

$$H_2C{=}CH_2 + 3\,O_2 \longrightarrow 2\,CO_2 + 2\,H_2O$$

Although many attempts have been made to discover the mechanism responsible for silver's unique action, opinions remain divided [78]. Evaluation of the various studies is difficult because often they were carried out under different conditions that were not always suitable for industrial purposes. It is agreed that silver can adsorb oxygen in a number of ways and that this phenomenon is the basis of its unequalled efficiency in catalyzing the oxidation of ethylene to ethylene oxide. The following adsorption forms of oxygen are of critical importance:

1) Atomic oxygen
2) Molecular oxygen
3) Subsurface oxygen, i.e., dissolved oxygen found below the surface

Opinions differ as to the role of these different types of adsorbed oxygen; two conflicting mechanisms have been proposed.

Mechanism 1. Only molecular oxygen reacts with ethylene to form ethylene oxide, whereas atomic oxygen only reacts to form carbon dioxide and water [79]. Chlorine (from the inhibitor) blocks the adsorption of atomic oxygen on the silver surface so that, in the ideal case, the optimally inhibited silver surface only adsorbs molecular oxygen (Eq. 3). The adsorbed molecular oxygen then reacts with ethylene to form ethylene oxide, leaving behind one oxygen atom after desorption (Eq. 4). This atomic oxygen then causes the combustion of ethylene to CO_2 and H_2O (Eq. 5).

$$6\,Ag + 6\,O_2 \longrightarrow 6\,Ag \cdot O_{2\,ads}$$

$$6\,Ag \cdot O_{2\,ads} + 6\,H_2C{=}CH_2 \longrightarrow 6\,\triangledown_{O} + 6\,Ag \cdot O_{ads}$$

$$6\,Ag \cdot O_{ads} + H_2C{=}CH_2 \longrightarrow 6\,Ag + 2\,CO_2 + 2\,H_2O$$

Since six oxygen atoms are needed for the complete oxidation of one ethylene molecule, six ethylene oxide molecules must be formed before one ethylene molecule can be completely oxidized. Therefore, if inhibition of atomic oxygen adsorption is optimal, the maximum selectivity is $6/7 \times 100 = 85.7\,\%$. This mechanism plausibly explains the way in which the inhibitor acts. For a long time the molecular oxygen mechanism was strongly supported by the fact that efforts to improve the catalysts and the process seemed to lead to selectivities approaching the limit of 85.7 % predicted by the mechanism, but not exceeding it.

A variant of this mechanism is based on the assumption that molecular oxygen can cause both ethylene oxide formation and total oxidation via a common intermediate [80], [81]:

The effect of the inhibitor is interpreted differently here. Reaction 2 requires a greater space than reaction 1. The inhibitor favors reaction 1 by reducing the available space on the surface of the catalyst. On an optimally inhibited surface, reaction 2 is totally suppressed, so that total oxidation takes place only via reaction 3. This results again in a maximum selectivity of 85.7 %.

Mechanism 2. In this mechanism, atomic oxygen, possibly together with the subsurface oxygen, is thought to be responsible for both total and partial oxidation. The contribution of the molecular oxygen, if any, is indirect [82], [83]. The environment of the adsorbed oxygen atom determines whether the reaction with ethylene

leads to ethylene oxide or CO_2 and H_2O [84], [85]. Chlorine (inhibitor), promoters, and subsurface oxygen in the proximity of the reacting oxygen atom are thought to influence the latter to favor partial oxidation, e.g., by reducing the negative charge of the adsorbed oxygen [86]. Unlike mechanism 1, the theoretical upper limit of selectivity of 6/7 does not apply for mechanism 2.

Since with modern catalysts (containing Cs, W, Re, and S in promoting quantities on the silver) maximum selectivities of 90 % are feasible even on an industrial scale, mechanism 1 can at least not exclusively be valid with these catalysts. Also, it has been shown that atomic oxygen, formed on the silver surface by decomposition of N_2O, can produce ethylene oxide, though with low selectivities [87], [88]. For the epoxidation of nobornene and styrene it has been shown under ultrahigh-vacuum conditions that the atomic oxygen species on the silver is responsible for the epoxidation [89], [90]. Furthermore, theoretical calculations seem to favor mechanism 2 and can explain the action of inhibitor and promotor [91], [92].

Intermediates of the total oxidation are thought to include acetaldehyde, acetic acid, formic acid, and oxalic acid [84]. Desorption of intermediates from the silver surface produces acetaldehyde when a helium stream is used; ethanol and acetic acid are produced when a hydrogen stream is used [93].

Formate, acetate, and oxalate were detected on a silver surface by ^{13}C NMR spectroscopy after contacting the silver first with oxygen and subsequently with ethylene [94].

Kinetics. Three reactions are usually considered in kinetic models:

1) Partial oxidation
2) Total oxidation
3) Consecutive oxidation

The consecutive combustion of ethylene oxide (3) is negligible only if temperatures are not too high and if the reaction takes place under chemical control. To avoid diffusion control low surface area catalyst supports with high pore diameters are required. The surface reaction leading to ethylene oxide is considered to be of the Langmuir – Hinshelwood type, that is, oxygen and ethylene are both adsorbed on the silver surface before reaction. Ethylene is not adsorbed on a clean, oxygen-free silver surface; this only occurs after preadsorption of oxygen. The reaction of ethylene with oxygen on the silver surface is also thought to be the rate-determining step in the absence of diffusion control. Kinetic data and models are available in the literature [95], [96], but these are usually restricted to very specific reaction conditions and catalysts, far from the complex situation of the industrial production. Ref. [97] describes kinetic studies with an industrial catalyst in different laboratory reactors to clarify the influence of the reaction products but does not take into account the influence of inhibitors, which is crucial to achieve high selectivities on an industrial scale.

4.3. Technology

An overview of the beginnings of commercial ethylene oxide production can be found in [1]. Production technologies for ethylene oxide plants based on the direct oxidation process are licensed by Shell, Scientific Design (SD), UCC, Japan Catalytic, Snam Progetti, and Hüls. Due to improved catalysts and production technology, large plants with capacities of up to 400 000 t/a can now be built.

The technologies are very similar, but differences exist, depending on whether air or pure oxygen is used for oxidation [44]. Shell plants use only pure oxygen, while Scientific Design and UCC have developed air-based oxidation plants as well. Figure 5 shows a simplified scheme for both the air- and oxygen-based processes. They both employ a recycle gas stream, which is continuously circulated through the reactors by compressors. The reactors consist of large bundles of several thousand tubes that are 6 – 13 m long and have an internal diameter of 20 – 50 mm. The catalyst is packed in the tubes

in the form of spheres or rings with a diameter of 3 – 10 mm; the initial selectivity of modern catalysts is ca. 80 – 90%, depending on the type of catalysts used. The catalysts are either very active, operating at an initial temperature of about 200 °C but with relatively low selectivities of 80 – 84 %, or they are highly selective but then need an initial temperature that is ca. 40 °C higher. Ethylene is converted at 200 – 300 °C and 1 – 3 MPa to produce ethylene oxide, CO_2, H_2O, and heat, as well as traces of acetaldehyde and formaldehyde; these products must be removed or separated from the recycle gas stream. The recycle gas is then reloaded with oxygen and ethylene and returned to the reactor.

Oxygen-Based Oxidation Process. At present, ethylene oxide is produced mainly by the oxygen-based process. The reactor tubes filled with the catalyst are surrounded by a coolant (water or a high-boiling hydrocarbon) that removes the reaction heat and permits temperature control. Heat is extracted either by pumping or by evaporating the coolant. If organic heat transfer media are used, the extracted energy is used to generate steam in secondary cycles, which is then employed for heating. The reaction heat also heats the recycle gas during its passage through the reactor. After leaving the reactor, the gas is likewise cooled by means of steam generation and/or used directly to heat the reactor inlet gases. Because of the different enthalpies of the partial and total oxidation reactions (see Section 4.1), the total available heat depends on the selectivity for the former (S) and amounts to $47\,250 - (434 \times S)$ kJ/kg ethylene.

Consequently, the quantity of energy released increases rapidly with decreasing selectivity. Therefore, the heat removal system must be sufficiently adaptable to cope with growing heat release in the reactor at rising reaction temperatures during the aging process of the catalyst, which is characterized by a decrease in its selectivity and activity in the course of its on-stream time. Temperatures on the coolant side (water or organic) of the catalyst tubes are restricted by the maximum design pressure, which usually does not allow temperatures higher than 300 °C. When the maximum temperature is reached the catalyst must be replaced.

After the gas from the reactor has been cooled, the ethylene oxide (1 – 2 %) and CO_2 (5 – 10 %) must be removed by scrubbing first with water and then with an aqueous potassium carbonate solution. In the ethylene oxide scrubber, virtually all of the ethylene oxide and small amounts of the other constituents of the recycle gas (CO_2, N_2, CH_4, CH_2CH_2, and aldehydes) dissolve in the water. The resulting aqueous ethylene oxide solution then passes to the ethylene oxide desorber. The ethylene oxide recovered as the head product in the desorber is subsequently stripped of its low-boiling components (i.e., the above-mentioned components of the recycle gas) and finally distilled, thereby separating into water and ethylene oxide.

A small proportion of the gas leaving the ethylene oxide scrubber (0.1 – 0.2 %) is removed continuously (combusted) to prevent the buildup of inert compounds (N_2, Ar, and C_2H_6), which are introduced as impurities with the reactants: ethylene (C_2H_6) and oxygen (Ar and N_2). The recycle gas from the scrubber is compressed, and a side stream is freed from carbon dioxide by further scrubbing with hot aqueous potassium carbonate solution. This leads to removal of the CO_2 not only by physical dissolution but also by reaction with potassium carbonate to give the hydrogencarbonate.

$$K_2CO_3 + CO_2 + H_2O \longrightarrow 2\,KHCO_3$$

The potassium carbonate solution, which is enriched with CO_2 is sent to the CO_2 desorber, where the CO_2 is stripped off at atmospheric pressure and is either released into the atmosphere or fed to a CO_2 utilization plant, after optional catalytic treatment (e.g., supported Pd/Pt) to remove residual hydrocarbons. The concentrations of the reactants in the bulk of the recycle gas, which is free from ethylene oxide and has a reduced CO_2 content, are restored to their starting levels by separate addition of oxygen, ethylene, inhibitor (1,2-dichloroethane, ethyl chloride or vinyl chloride), and if necessary, a diluent (CH_4). The gas is then returned to the reactor.

The oxygen that is used must be extremely pure (> 99 %) and is obtained by air separation. Nevertheless, a purge stream of recycle gas is still necessary due to the presence of traces of N_2 and Ar. Oxygen is added in a special mixing device that ensures rapid homogenization with the recycle gas. This is necessary because the explosive limit is locally exceeded at the mixing point.

Figure 5. Flow scheme for ethylene oxide production by the oxygen-based or air-based oxidation of ethylene
a) Reactor; b) Ethylene oxide scrubber; c) CO_2 scrubber; d) CO_2 desorber; e) Off-gas purification; f) Air purification; g) Primary reactor; h) Primary ethylene oxide scrubber; i) Secondary reactor; j) Secondary ethylene oxide scrubber; k) Ethylene oxide desorber; l) Stripping column; m) Ethylene oxide distillation

The ethylene is also usually very pure (> 99.5 %) and must be free from the strong catalyst poisons sulfur and acetylene. Methane, used as a diluent, also must be free from sulfur compounds.

Natural gas is used as methane source and usually requires cleaning steps to attain the required purity. Sulfur compounds, which poison the catalyst irreversibly, are removed by adsorption beds. Higher hydrocarbons, which affect the reactor performance, mainly by removing the chlorine inhibitor from the silver surface, are removed by distillation or with molecular sieves.

Air-Based Oxidation Process. The air-based process is similar to the oxygen process, but some differences exist. Air introduces a large amount of nitrogen into the recycle gas, which means that a large amount of purge gas must be vented to maintain a constant nitrogen concentration in the recycle stream. The quantity of gas that is vented removes sufficient CO_2 to make CO_2 scrubbing unnecessary. However, the off-gas leaving the primary reactor still contains so much ethylene that it must be further converted in a subsequent secondary or purge reactor before it can be vented into the atmosphere.

The reaction conditions cannot be tailored to the needs of ethylene oxide formation as optimally as in the oxygen-based process. The conversion of ethylene is higher than in the oxygen-based process, especially in the secondary reactors, so as to obtain an acceptable level of ethylene loss in the purge gas. Since selectivity is inversely related to ethylene conversion, it follows that the air-based process has a lower selectivity.

The conditions and gas compositions used in the oxygen- and air-based processes are listed in Table 5.

Table 5. Operating parameters used in the air-based and oxygen-based production of ethylene oxide

Parameter	Air-based process	Oxygen-based process
C_2H_4 concentration, vol %	2 – 10	15 – 40
O_2 concentration, vol %	4 – 8	5 – 9
CO_2 concentration, vol %	5 – 10	5 – 15
C_2H_6 concentration, vol %	0 – 1	0 – 2
Ar concentration, vol %		5 – 15
CH_4 concentration, vol %		1 – 60
Temperature, °C	220 – 277	220 – 275
Pressure, MPa	1 – 3	1 – 2.2
GHSV ∗, h^{-1}	2000 – 4500	2000 – 4000
Pressure drop, kPa,	40 – 200	
C_2H_4 conversion, %	20 – 65	7 – 15
Selectivity, %	80	80 – 90

∗ GHSV = gas hourly space velocity.

Reactor. Since oxidation of ethylene is highly exothermic, reaction in a fluidized bed would appear to be appropriate. However, attempts to develop such a process on a commercial basis have not produced any advantages for selectivity [98], [99] and have led to problems due to abrasion and sintering. As a result, all ethylene oxide plants currently employ fixed-bed tubular reactors. The diameter of the tubes must not be excessive so as to ensure sufficient heat transfer to the heat transfer medium. A tube diameter of 20 – 40 mm is common. The diameter of the catalyst particles has an upper limit determined by the need for satisfactory gas mixing and a lower limit resulting from an increasing drop in pressure. A diameter of 3 – 8 mm is used.

Cooling. Each of the two possible heat extraction systems – circulation or evaporation of the coolant – has its advantages and disadvantages. Coolant circulation requires a large amount of liquid (pumping power), but allows a defined temperature increase in the direction of gas flow. Ethylene and oxygen concentrations in the cycle gas decrease on passage through the reactor; this leads to lower conversion, which can be compensated by controlled temperature increase toward the reactor outlet.

In evaporative cooling, an organic coolant (e.g., isododecane) or water is used. The reaction temperature is controlled very effectively by a control valve that keeps the pressure of the boiling coolant at the appropriate pressure. The whole temperature range from 190 to 290 °C, required by the aging catalyst, can be covered by evaporative cooling. Organic coolants with a boiling point of about 190 °C at atmospheric pressure are used. The hydrostatic height of the coolant in the reactor results in an unavoidable temperature increase towards the bottom of the reactor. Since evaporation extracts heat more efficiently than circulation, evaporative cooling requires a smaller volume of circulating coolant. The axial temperature differences can be minimized more easily. Large amounts of liquid coolant leave the reactor with the coolant vapor. The liquid is recovered in a separator and returned to the reactor. The coolant present in the reactor and in the separator constitutes a safety reserve during uncontrolled increases in ethylene conversion in the reactor ("runaway").

The flammability of organic coolants is a clear disadvantage compared to water, especially at the necessary high temperatures. However, water results in much higher pressures on the coolant side and hence higher apparatus costs.

When organic coolants are used, the coolant vapors are condensed in heat exchangers producing steam, after which the liquefied coolant is returned to the reactor. The steam serves to heat distillation columns in the plant. If water is used as coolant the steam leaving the reactors can be used directly. The higher the selectivity of the catalyst, the more steam must be imported into the plant.

Improved catalysts with high activities and selectivities operate at a lower temperature (ca. 220 °C) and allow smaller reactor volumes. This has encouraged the use of water-cooled reactors; however, organic heat transfer media (e.g., Dowtherm) are still widely employed. A detailed discussion of heat transfer with organic heat transfer media in terms of optimum selectivity and safety can be found in [100].

Ethylene Conversion. The selectivity of ethylene oxide formation depends on ethylene conversion. Selectivity decreases more or less linearly with increasing ethylene conversion [101]. Therefore, the highest selectivities are achieved with minimum conversions, but the resulting ethylene oxide concentrations are then too low for commercial purposes. Thus, ethylene conversion is chosen to achieve ethylene oxide concentrations of 1 – 3 vol % at the reactor outlet.

Byproducts. Besides large quantities of CO_2 produced by total oxidation of ethylene, ethylene glycols and small amounts of acetaldehyde and formaldehyde are formed and must be processed in ethylene oxide plants. The acetaldehyde stems from isomerization of ethylene oxide, catalyzed by the catalyst support and by rust on apparatus walls. Formaldehyde is produced by oxidation of ethylene oxide with and without participation of the wall surface [102]. Ethylene glycols are unavoidably produced when ethylene oxide is scrubbed from the recycle gas with water and is subsequently stripped from the aqueous solution by heating. Monoethylene glycol [*107-21-1*],

diethylene glycol [*111-46-6*], triethylene glycol [*112-27-6*], and higher poly(ethylene glycols) are formed when ethylene oxide comes into contact with water [103] (→ Ethylene Glycol). Some of the cycle water must be bled off continuously and the ethylene glycol removed to prevent it from accumulating (see Fig. 5). This glycol is of inferior quality to that synthesized by ethylene oxide hydrolysis. Special methods for purifying the resulting glycols have been described, e.g., treatment with ion exchangers and activated charcoal [104].

Materials. Since ethylene oxide is noncorrosive, the reactors and the sections of the plant that convey ethylene oxide are usually made of mild steel. To reduce the formation of acetaldehyde by isomerization of ethylene oxide on rust, stainless steel is increasingly being used for the reactors and the ensuing cycle gas lines, where temperatures are highest. The sealing materials for valves, flanges, and pumps must be chosen carefully [105]. Many materials used in chemical industry for O-rings, packings, and gaskets are not resistant to the influence of ethylene oxide and have been the cause of severe incidents [106]. The materials in the system used to remove the carbon dioxide must also be carefully selected because of possible CO_2 corrosion [107].

If rust is present in steel tubes or containers, polymer formation [38], increased viscosity, and brown discoloration are to be expected.

Current plant design is predominantly tailored to the oxygen-based process because this is normally more economical than the air-based process. In exceptional cases, however, the air-based process may be preferred depending on local factors (e.g., the availability of oxygen) [108].

Possible Developments. Alternative routes from ethylene to ethylene oxide are being studied, e.g., Tl(III)-catalyzed oxidation in solution [108], electrochemical oxidation [109], and enzymatic oxidation [110]. However, these processes appear to be far from industrial application. About half of the ethylene oxide produced is converted into ethylene glycol. Alternative syntheses for ethylene glycol based on carbon monoxide, formaldehyde, and ethylene are being developed [111–114] (→ Ethylene Glycol); these are more promising than those for ethylene oxide. With increasing raw material prices, the appearance of an economical alternative is foreseeable. Naturally, such an alternative would have an adverse effect on ethylene oxide capacities, but the economics of ethylene oxide production could be improved by

1) Selective production of monoethylene glycol from ethylene oxide, without the formation of higher ethylene glycol homologues, e.g., via glycol carbonate [44]
2) Reducing energy consumption
3) Improving the selectivity, capacity, life-span, and activity of the catalysts

5. Environmental Protection and Ecology

Ethylene oxide plants using the direct oxidation process represent a clear environmental improvement over the chlorohydrin process. Environmental and other important aspects of ethylene oxide production are discussed in EPA studies [115]. Both oxygen- and air-based plants emit two main off-gas streams: recycle vent gas and CO_2. In the oxygen-based process, ca. 70 % of the recycle vent gas consists of hydrocarbons (ethylene and methane), which can be combusted (by torch or in a steam generator). The corresponding off-gas in the air-based process is produced in considerably greater quantities, but contains only up to ca. 2.3 % hydrocarbons. It can be purified by catalytic oxidation. The CO_2-rich vent gas in the oxygen-based process contains ca. 0.2 % hydrocarbons. This concentration can be reduced substantially by depressurizing the CO_2-rich absorbent in two steps. The gas from the first step is rich in hydrocarbons and is recycled, only the gas from the second step is vented [116]. A catalytic treatment (e.g., supported Pd/Pt) may be required by environmental regulations to remove hydrocarbons before the CO_2 is released to the atmosphere but may also be necessary to ensure the purity of the CO_2 for further use. The CO_2-rich vent gas stream from air-based plants is produced in much smaller quantities and contains ca. 5 % hydrocarbons that can be removed by combustion. Ethylene oxide can be removed from waste gases, such as are generated during sterilization, by combustion with oxygen [117] or by an acid scrub [118],

[119], [121]. Biodegradation of the ethylene glycol generated during ethylene oxide hydrolysis presents no difficulties. If ethylene oxide occurs as a mixture with fluorohydrocarbons, recovery by drying and subsequent compression is recommended [120]. Methods for handling ethylene oxide reaction vessels without the release of vent gas have been described [122].

Ethylene oxide is toxic to microorganisms and fish [123]. The LC_{50} value for fish (*Pimephales promelas*) is 84 mg/L (exposure time 96 h). However, in free-flowing waters the ethylene oxide concentration decreases continually (after 4 h at 25 °C in moving water, the concentration drops by ca. 95 %) due to a combination of evaporation, hydrolysis (half-life at 25 °C ca. 14 d), and biodegradation. The ethylene glycol produced as a result of ethylene oxide hydrolysis is considerably less toxic to aquatic organisms ($LC_{50} > 10\,000$ mg/L) and is readily biodegradable. Effluents (e.g., from ethylene oxide production plants [115]) containing ethylene oxide are therefore treated biologically after the ethylene oxide has been converted into ethylene glycol.

Degradation of ethylene oxide in air is relatively slow and thought to proceed mainly by a slow reaction with hydroxyl radicals. Disregarding other removal mechanisms, this results in a lifetime of 330 d. The reaction with ozone is too slow to represent a significant removal pathway [124]. Another report indicates a lifetime of 100 – 200 d [125]

According to TA Luft [126], vent gas streams must not contain more than 25 g/h or 5 mg/m^3 ethylene oxide.

6. Quality Specifications

Ethylene oxide is a major industrial product that is obtained with a consistently high purity irrespective of the production process used. Typical specifications are given in Table 6.

Table 6. Typical specifications of ethylene oxide

Appearance	clear, colorless
bp at 101.3 kPa	10.8 °C
Water content ∗	50 mg/kg
CO_2 content ∗	10 mg/kg
Aldehyde content ∗	50 mg/kg
Ethylene oxide content (min.) ∗	99.5 %

∗ As determined by gas chromatography.

7. Analysis

An overview of analytical methods for ethylene oxide can be found in [127]. An established method for determining ethylene oxide is based on its reaction with $MgCl_2$ [128]. In view of the low TRK value (5 mg/m^3), accurate methods are needed to determine traces of ethylene oxide in air.

An adsorption chromatography method is reported to be suitable for concentrations exceeding 0.15 ppm [129]. The NIOSH method 1607 [134] with a working range of 0.04 – 1.7 ppm (0.09 – 3 mg/m^3) is based on adsorption with charcoal, derivatization with HBr to give 2-bromoethanol, and gas chromatography. The CS_2 used in the NIOSH method can be replaced by *N*,*N*-dimethylacetamide [130]. Methods using adsorption on charcoal are susceptible to the influence of temperature and humidity [131], [132].

A field comparison of four methods of monitoring ethylene oxide by portable devices – two passive monitors, one sorbent tube (OSHA), and one GC method (NIOSH) – showed their viability for measuring the workplace concentration for short-term and full-shift exposure [133].

Exposition to ethylene oxide can be monitored by the detection of (2-hydroxyethyl) valine in hemoglobin, the method resulting in accurate data of time-integrated exposure [39].

8. Handling, Storage, and Transportation

Ethylene oxide has repeatedly caused serious explosions, fires, and accidents [106], [135], [136]. It is an extremely hazardous substance because it can explode and is both highly flammable and extremely reactive (exothermic reactions). Aqueous solutions containing > 4 wt % ethylene oxide are flammable; flash points are given in Table 2. Furthermore, ethylene oxide is toxic and poses a danger both to health and to the environment. The inherent hazards of the product must be known; all prescribed safety measures and legal requirements must be observed. Personnel handling ethylene oxide must receive appropriate training.

Safety precautions for handling ethylene oxide and its dangerous properties are described in detail in the data sheets provided by the manufacturers (e.g., [106], [137]) and elsewhere (e.g., [105], [138–141]). Therefore, only the most important points are discussed here.

Explosion and Fire Control. Pure ethylene oxide vapor or ethylene oxide vapor mixed with air or inert gases can decompose explosively. Explosiveness depends on pressure, temperature, concentration, the type, form, and energy of the ignition source, and the type of container. High pressure can be generated on explosion of ethylene oxide; therefore, for safe handling the exact explosive limits must be known. Pure ethylene oxide vapor at 101.3 kPa decomposes when passed through a heated platinum coil [142]. The temperature at which decomposition starts (decomposition temperature) was calculated to be 571 °C. Calculations were based on the temperature at the tube exit and the thermodynamic data for ethylene oxide and its decomposition products. The thermal decomposition of ethylene oxide and ethylene oxide – nitrogen mixtures has been investigated [143]. If ethylene oxide vapor is introduced into a preheated vessel at 101.3 kPa, explosive decomposition takes place at ca. 500 °C [143]. The decomposition temperature is reduced by an increase in the pressure (e.g., ca. 450 °C at 1 MPa) but is increased by the addition of nitrogen. Explosive thermal decomposition is still possible below atmospheric pressure, but the necessary temperature then increases above 500 °C.

The ignition properties of ethylene oxide and its mixtures with air and inert gases have been studied by several authors. Pure ethylene oxide vapor can ignite even at a pressure as low as 48 kPa (electric spark) or 20.2 kPa (mercury fulminate) [144]. The maximum theoretical explosive pressure is ca. 10 times the inital pressure, but can increase to 20 times the initial pressure if liquid ethylene oxide is present. This phenomenon occurs because liquid ethylene oxide evaporates and participates in the decomposition reactions that take place in the vapor phase [145]. Mixtures of ethylene oxide with N_2, CO_2, methane, and air do not ignite over certain concentration ranges; the upper explosive limit is always 100 % ethylene oxide, since pure ethylene oxide also decomposes if ignited. In the presence of oxygen (air), combustion and decomposition take place simultaneously and the ignition temperature (or energy) is reduced. The ignition temperature of ethylene oxide in air at 101.3 kPa is 429 °C [146]. As the ethylene oxide concentration increases, the proportion destroyed by decomposition also increases [21], [147]. The minimum value cited for the lower explosive limit of ethylene oxide – air mixtures is 2.6 % [148]; the explosive range of ethylene oxide – air mixtures is accordingly 2.6 – 100 %. Figures for an upper explosive limit of ca. 80 % at 101.3 kPa are probably due to differences in the apparatus and methods used [149–151].

Figure 6. Recommended total pressure for the safe storage of ethylene oxide as a function of the temperature after blanketing with nitrogen

Explosive decomposition of ethylene oxide in closed containers can be suppressed by blanketing with an inert gas until the total pressure of the nonexplosive range is reached. Blanketing agents with higher thermal conductivities suppress explosions more effectively. Quotation of the minimum total pressure necessary for inert gas blanketing is important; values cited in [21]

were obtained without consideration of the pressure and temperature dependence and, therefore, do not apply at higher pressures. Figure 6 shows the total pressure currently recommended for inert gas blanketing of ethylene oxide with nitrogen as a function of temperature [105]. The explosive limits of other mixtures of ethylene oxide with inert gases and air can be found in the literature, e.g., ethylene oxide with H_2O [152]; N_2 [143], [152]; N_2-H_2O [144]; CO_2-H_2O [144]; CH_4 [145]; CO_2 [21], [152], [153]; C_3H_6 [154]; C_4H_9 [154]; N_2 – air [21]; CH_4 – air [21]; CO_2 – air [148]; CF_2Cl_2 – air [151], [155].

As has already been explained, liquid ethylene oxide can participate in the decomposition that is initiated in the vapor phase. Explosion of liquid ethylene oxide initiated by an ignition source within the liquid was first described in 1980 [156], [157], but once again, the decomposition reaction is thought to take place in the gas phase created by the source of ignition and is maintained by the subsequent evaporation of ethylene oxide. Figure 7 shows the temperature limits for ignition of liquid ethylene oxide as a function of the pressure. At pressures between 10 and 15 MPa, the ignition temperature decreases rapidly. This phenomenon is presumed to be due to the fact that the critical state is reached. The conditions under which liquid ethylene oxide is usually produced, stored, or processed lie within the nonexplosive range (Fig. 7).

Figure 7. Explosive limits for pure liquid ethylene oxide as a function of pressure and temperature

The highly exothermic reactions of ethylene oxide represent a further hazard [135]. If traces of polymerization initiators (e.g., amines) find their way into a large supply of ethylene oxide (e.g., in a tank), polymerization starts slowly and then accelerates because of the resulting temperature increase. Polymerization proceeds quasi-adiabatically, leading to sudden and rapid increases in temperature and pressure that can rupture the container [158], [159], which may be followed by explosive decomposition of the released ethylene oxide vapor (see Fig. 8).

Figure 8. Runaway reactions of ethylene oxide (EO) [169] a) Dewar polymerizaation of EO (10 ml)/NaOH (0.02 g)/H_2O [167]; b) Calculated adiabatic reaction of EO (40 %) in H_2O (initial temperature 27 °C) [168]; c) Polymerization of EO/NMe_3 (0.184 %)

Although rust is only a mild catalyst for ethylene oxide polymerization, its presence in heat exchangers or other hot equipment can lead to ignition of the ethylene oxide vapor by a combination of polymerization and disproportionation to C_2H_4, CO_2, H_2, and H_2O (explosion in the UCC plant, Seadrift, 1991). γ-Fe_2O_3 and γ-FeOOH are the active species in this reaction [160].

Insulation fires can occur if ethylene oxide leaks into insulating material such as asbestos, magnesium silicate, calcium silicate, and mineral wool by a combination of effects and reactions. Like other organic compounds, ethylene oxide can have considerably lower autoignition temperatures in insulation material than otherwise [161], [162]. Isomerization of ethylene oxide to acetaldehyde in the presence of rust results in an additional decrease in the autoignition temperature [141]. In the presence of water, ethylene oxide may be hydrolyzed to ethylene glycol and subsequently polymerize to poly(ethylene glycols) with evolution of heat. Eventually, the organic material collected in the insulation (ethylene oxide, acetaldehyde, glycols) may be oxidized by air. The resulting hot spots on the surface of the apparatus can trigger an explosive decomposition of ethylene oxide vapor in the column (explosion in the BP plant, Antwerp,

1987 [163] and in the BASF plant, Antwerp, 1989 [164]). To avoid these risks, special insulating material with a low specific surface and closed cells (glass foam) is used, and special methods for insulation have been developed. A gap between the outer wall of the apparatus and the insulation prevents accumulation of organic material in the insulation and allows monitoring of organic compounds in the gap.

The accidents in ethylene oxide plants also initiated a fundamental reevaluation of the distillation section. The use of structured packing instead of trays can prevent the propagation of ethylene oxide decomposition. A beginning decomposition in the column can be recognized in time to be quenched with water [165], [166].

Because of the above-mentioned hazards, the following potentially dangerous situations must be prevented:

1) Leakage of liquid or gaseous ethylene oxide
2) Entry of air, oxygen, or reactive impurities into ethylene oxide containers
3) Ignition sources in danger areas
4) Overheating of ethylene oxide (chemical reaction, fire, etc.)

Leaks or spills should be promptly diluted with sufficiently large volumes of water to reduce the ethylene oxide concentration to less than 4 wt %. Mixtures of ethylene oxide and water will still burn if the ethylene oxide concentration exceeds 4 wt %. Fires should also be extinguished with large volumes of water, carbon dioxide extinguishers can be used for small fires.

Storage and Transportation. Ethylene oxide is transported in tank cars and containers and can be conveyed by rail or by sea and, in many countries, also by road. In Germany, conveyance by road is possible with special permission and under certain conditions (GGVS/ARD § 7). Hazard classifications for ethylene oxide follow:

Water hazard class	WGK 2 (no. 235)
CFR 49	no. 172.101, flammable liquid
GGVS/GGVE/RID/ADR	class 2, no. 4 ct
ADNR	class 2, no. 8 AF
EMS	2-06
MFAG	365
GGVSee, IMDG Code	class 2
UN no.	1040
JATA no.	722
Temperature class (DIN 57 165)	2
Explosion limit (DIN 57 165)	IIB

Storage and transport containers for ethylene oxide are usually made from steel, but steel is suitable only if special measures have been taken to prevent rust formation [38]. Rust acts as a mild polymerization catalyst and is dispersed in the ethylene oxide by polymerization starting on available surfaces. Polymer concentrations as low as ca. 110 mg/kg produce an increase in viscosity, may cause brown discoloration, may block filters, valves etc., and form deposits on the container walls. Therefore, steel containers should be blasted before first use, the blasting residues carefully removed, and the container flushed with nitrogen. Stainless steel is increasingly being used to avoid these problems. When aqueous solutions of ethylene oxide are handled, precipitation of solid hydrates (cf. Table 2) may cause blockages.

In Europe, tank cars are tested at a pressure of 1.6 MPa and they must be protected from the sun by a protective roof or insulation (GGVE). Ethylene oxide – nitrogen mixtures can be transported at a maximum pressure of 1 MPa at 50 °C (GGVS/RID). The proportion of nitrogen in the vapor phase must be high enough to ensure that explosion cannot occur at or below this temperature. In the United States railroad tanks are insulated and equipped with pressure-release valves.

Safety measures that should be observed when reactions with ethylene oxide are performed or when it is used for sterilization can be found in [105].

Personal Protective Equipment. To avoid skin contact with ethylene oxide, goggles as well as protective clothing (gloves, boots, suits, aprons) have to be used. As ethylene oxide permeates easily through most materials, the choice of an adequate material is crucial. Butyl rubber is normally a suitable material, but as quality and thickness play an important role, a test of the permeation resistance against ethylene oxide is recommended before use.

Leather clothing and footwear represent an often neglected risk when contacted with ethylene oxide or its aqueous solution, because the severe and slowly healing damage to the skin appears only after a induction period of many hours. Therefore leather articles must be discarded at once when contaminated with ethylene oxide. Other clothing contaminated with ethylene oxide must be taken off immediately and

discarded or decontaminated. Immediate flushing with copious water can avoid detrimental action on eyes and skin.

If ethylene oxide concentrations of 0.25 ppm in the air are reached, respiratory equipment must be used [170]. Gas masks are permitted only up to certain exposure limits, and their duration of use is restricted according to the ethylene oxide concentration [171]. Beyond a certain concentration level, equipment has to be used which is independent of the ambient atmosphere (e.g., positive-pressure self-contained breathing apparatus) [172]. Also above ethylene oxide concentrations of 0.25 ppm restrictions in the employment of juveniles and pregnant women are effective [170].

Figure 9. Uses of ethylene oxide

9. Uses

Ethylene oxide is an excellent disinfectant, sterilizing agent, and fumigant when it is used as a nonexplosive mixture with N_2, CO_2, or dichlorofluoromethane. The gas penetrates into pores and through packaging or clothing. It can be used, for example, to sterilize surgical instruments in hospitals or to remove pests and microorganisms from spices, furs, etc.

However, most ethylene oxide is converted into other products. Figure 9 shows the percentages of ethylene oxide used in these derivatives in the United States. Although this distribution was determined in 1978, it still applies today and is typical of the world market.

Products derived from ethylene oxide have many different uses, only the most important ones are listed here:

Monoethylene glycol [*107-21-1*] [173]: Antifreeze for engines, production of poly(ethylene terephthalate) (polyester fibers, foils, and bottles), and heat transfer liquids.

Diethylene glycol [*111-46-6*] [174]: Polyurethanes, polyesters, softeners (cork, glue, casein, and paper), plasticizers, gas drying, solvents, and deicing of aircraft and runways.

Triethylene glycol [*112-27-6*] [175]: Lacquers, solvents, plasticizers, gas drying, and humectants (moisture-retaining agents).

Poly(ethylene glycols) [176]: Cosmetics, ointments, pharmaceutical preparations, lubricants (finishing of textiles, ceramics), solvents (paints and drugs), and plasticizers (adhesives and priinks).

Ethylene glycol ethers [177]: Brake fluids, detergents, solvents (paints and lacquers), and extractants for SO_2, H_2S, CO_2, and mercaptans from natural gas and refinery gas.

Ethanolamine [*141-43-5*] : Chemicals for textile finishing, cosmetics, soaps, detergents, gas purification (H_2S, SO_2, and CO_2).

Ethoxylation products of fatty alcohols, fatty amines, alkyl phenols, cellulose, poly(propylene glycol) [28]: Detergents and surfactants (nonionic), biodegradable detergents, emulsifiers, and dispersants.

Ethylene carbonate [*96-49-1*] : Solvents.

10. Economic Aspects

In 1980, ca. 16 % of world ethylene production was used to synthesize ethylene oxide; this use was second only to polyethylene production (44 %). World production of ethylene oxide in 2000 was ca. 15×10^6 t/a. Ethylene oxide is an important raw material for major consumer goods in virtually all industrialized countries. Table 7 gives an overview of worldwide ethylene oxide capacities. Excess capacities were already apparent in 1984 [178].

11. Toxicology and Occupational Health

The toxicological properties of ethylene oxide are mainly determined by its reactivity with nu-

cleophilic groups such as carboxyl, amino, phenolic hydroxide, or sulfhydryl groups.

In humans, acute inhalative poisoning causes headache, nausea, and vomiting within a few minutes [179–181]. Local irritation results in dyspnea [182]. Myocardial damage [183], excitation, numbness, and finally coma [179] follow. After dermal exposure, blisters are formed on the skin, and symptoms similar to those found after inhalation appear due to skin absorption [184]. Sensitization has been reported after repeated dermal contact [185]. Repeated inhalation of ethylene oxide leads to sensory-motor polyneuropathy and impaired memory [186], [187]. Cataracts may be formed after chronic exposure [188].

Oral Toxicity. The acute oral toxicity (LD_{50}) of ethylene oxide in the rat is 330 mg/kg [189].

Inhalation. The 4-h LC_{50} value is 835 mL/m^3 in the mouse and 1460 mL/m^3 in the rat [190]. Acute symptoms largely resemble those observed in humans. Subchronic administration of ethylene oxide (100 and 200 mL/m^3) to cats by means of inhalation for a period of 22 days produced anorexia, apathy, atoxia, and paralysis of the hind quarters [191]. Lethalities also occurred, postmortem examination revealed liver and kidney damage accompanied by hyperemia and perivascular bleeding in various organs (e.g., the brain) [191]. Rodents that inhaled air containing ethylene oxide at a concentration of 300 – 400 mL/m^3 displayed additional

local irritation and severe, primary neurotoxic atrophy of the musculature in their hind quarters [190]. Hemotoxic effects have also been observed in rodents [192]. Monkeys exposed to inhalative concentrations of 204 mL/m^3 for up to 226 days showed impaired reflexes, reduced sensitivity to pain, and neurotoxic muscular atrophy of their hind quarters [193].

Teratogenicity. In studies on rats exposed to maximum inhalative concentrations of 100 [194] or 150 mL/m^3 [195], symptoms of intolerance were observed in the dams but no malformations were observed in the fetuses. Ethylene oxide does not produce teratogenic effects in rabbits [195].

Mutagenicity. Ethylene oxide is mutagenic due to its alkylating properties. It alkylates the germ cells of male rats [196] and produces mutations in *Drosophila melanogaster* [197], *Neurospora crassa* [198], and *Salmonella typhimurium* (Ames test) [199], [200]. Dominant lethal mutations and chromosome aberrations are induced in male rats [201]. Increased numbers of micronuclei are found in the polynuclear erythrocytes of rats [202] and mice [203], [204]. Chromosomal defects are induced in cultured amniotic cells from humans [205]. Increased exchange between sister chromatids is found in monkeys and rats [206], [207]; the same effect is observed in workers who have been exposed to ethylene oxide (cumulative dose 0.5 – 50 g) [208–211].

Carcinogenicity. A large number of reports have been published on the carcinogenic properties of ethylene oxide in animals. Dilute ethylene oxide applied to the skin of rats did not induce tumor formation [212]. Subcutaneous injection of ethylene oxide in rats did not have any systemic carcinogenic effects [213], [214]. However, intragastric administration led to an increase in the incidence of epithelial carcinomas in the gastric mucosa [215]. An increased incidence of brain tumors and mononuclear cell leukemia was found in rats that had inhaled ethylene oxide at concentrations of 10, 33, or 100 mL/m^3 over a period of two years [216]. An increased incidence of peritoneal mesotheliomas was also observed in the animals exposed to concentrations of 33 and 100 mL/m^3. Results of human epidemiological studies on workers exposed to ethylene oxide differ [217–220]. Ethylene oxide is classified as a "putative human chemical carcinogen" [221].

Permissible Exposure Limits. Ethylene oxide is classified as a class 2 carcinogen by the German MAK commission (TRK = 1 mL/m^3 = 2 mg/m^3) and as a class A2 carcinogen by the ACGIH (TLV-TWA = 1 mL/m^3 = 2 mg/m^3)[222].

1. Introduction

2-Ethylhexanol (2-ethyl-1-hexanol) [*104-76-7*], $C_8H_{18}O$, M_r130.23, ranks after the lighter alcohols (methanol to butanol) as the most important synthetic alcohol (see also → Alcohols, Aliphatic) [1–3]. Approximately 2×10^6 t/a are produced worldwide. 2-Ethylhexanol is mainly used as the alcohol component for the manufacture of ester plasticizers for soft poly(vinyl chloride) (PVC) and has been produced for this purpose since the mid-1930s.

2-Ethylhexanol

The raw material for the synthesis of 2-ethylhexanol, namely butyraldehyde (butanal) [*123-72-8*], is made almost exclusively from the petrochemical feedstock propene via the oxo synthesis (→ Butanals). The route from ethylene via acetaldehyde is insignificant. This situation could change if acetaldehyde produced from ethanol (via fermentation or homologation of methanol) and coal-based synthesis gas (which is already used for the oxo synthesis) becomes available at a reasonable price.

Acetaldehyde was formerly produced from coal via acetylene. This synthesis route had no chance of competing successfully against the route based on petrochemical raw materials because of the large number of steps involved.

2. Properties

Physical Properties. 2-Ethylhexanol is a clear liquid with a characteristic odor and forms a transparent mixture with other alcohols, ethers, and most organic liquids. Its main physical properties are summarized in Tables 1 and 2.

Chemical Properties. 2-Ethylhexanol reacts in the typical manner of α-branched primary alcohols (→ Alcohols, Aliphatic, Chap. 2.2. and → Alcohols, Aliphatic, Chap. 2.3.).

3. Industrial Production

2-Ethylhexanol is produced in four steps:

1) Aldolization of butyraldehyde and subsequent dehydration
2) Separation of the aldolization solution
3) Hydrogenation of unsaturated 2-ethyl-2-hexenal as an intermediate product
4) Fractionation of 2-ethylhexanol

	80	2.68

The butyraldehyde required for the aldolization stage is made by hydroformylation of propene. In addition to processes using cobalt as a catalyst [5–8], processes that employ rhodium catalysts [9–12] have gained increasing significance since the 1980s.

The demands placed on the purity of 2-ethylhexanol are so high that the purity of the starting product, butyraldehyde, is also extremely important. Isobutyraldehyde is formed to a greater (cobalt catalysts) or lesser (rhodium cata-lysts) extent during hydroformylation and must be separated to prevent mixed aldolization. Therefore, special processes in which aldolization and, in some cases, hydrogenation occur in parallel with hydroformylation are becoming less important [5], [13], [14].

Older processes based on acetylene that involve the intermediate stages acetaldehyde/crotonaldehyde would permit access not only to coal as a raw material, but also to petrochemistry via ethylene [15], [16] as well as to regenerable raw materials via ethanol. However, these processes are not currently important.

The major oxo producers [17–19] all offer processes for the manufacture of 2-ethylhexanol that differ only in certain details. Figure 1 shows the flow diagram for a 2-ethylhexanol plant.

Figure 1. 2-Ethylhexanol plant
a) Aldolization; b) Phase separator; c) Hydrogenation; d) Distillation

In the aldolization reactor, butyraldehyde reacts very quickly to give 2-ethyl-2-hexenal, aqueous sodium hydroxide being employed as the standard industrial catalyst. Local overheating in the reaction mixture must be avoided, since this may cause secondary reactions and thus decrease yields. Thorough mixing of the two-phase system is necessary. The primary aldol addition must take place rapidly; the immediately ensuing dehydration of the hydroxyalde-

hyde must be conducted as quickly and quantitatively as possible because the aldol is unstable and can impair the product quality and yield.

The aldolization reactor may be a mixing pump [20], a packed column [7], or a stirring vessel [21], [22].

The various processes operate at a temperature of between 80 and 150 °C and pressures below 0.5 MPa. The ratio of aldehyde to aqueous sodium hydroxide solution is 1 : 10 – 1 : 20. Under these conditions, conversion rates >99 % are obtained. The heat of the aldolization reaction is used for steam generation.

After the aldolization stage in (a) (see Fig. 1), the mixture is separated in a phase separator (b) into an upper organic phase and a lower aqueous phase containing the aldolization solution. Part of the aldolization solution can be recycled, but the rest must be removed from the system via a side stream because the aldolization solution is diluted by the water that is produced in the reaction; the aldolization byproducts (Cannizzaro and Tischchenko reactions) must also be removed. Sodium hydroxide is added to maintain its concentration at 2 – 4 %.

The side stream has such a high COD value (e.g., due to its sodium butyrate content) that it should be subjected to preliminary purification before being conveyed to a biological treatment plant. Suitable purification methods are oxidation, acid treatment, and extraction which allows partial recycling of valuable products.

The organic product from the phase separator (b) can either be hydrogenated in a single stage on a fixed nickel catalyst [9] or in several stages either in a combination of gas – liquid phases [23] or liquid – liquid phases (sump-phase or trickle-bed reactor). The heat of reaction for the hydrogenation of the C = C double bond and the aldehyde group is relatively high, 178 kJ/mol. Temperature control problems may therefore arise as local overheating decreases yields and must be avoided.

With single-step hydrogenation, remixing with the hydrogenation product has been proposed to dissipate heat (150 – 200 °C) [7]; in contrast to other processes, medium pressure is initially necessary to ensure adequate conversion. Modern plants normally utilize two stages to remove residual amounts of carbonyl compounds and to ensure that high-grade 2-ethylhexanol is obtained [2]. Nickel [7], [24], [25], copper [26] or mixed systems [23], [27–30] are preferred as heterogeneous hydrogenation catalysts. The heat of the hydrogenation reaction is also used for steam generation. In the hydrogenation stage, a conversion of 100 % and a selectivity of >99 % is attained.

Fractional distillation of the hydrogenation product from (c) in (d) normally takes place in three stages: In the first stage, the light ends are separated at the head and can be employed for the manufacture of 1-butanol. In the second stage, pure 2-ethylhexanol is collected at the head. In the third stage, the recyclable intermediate fractions are separated from the heavy oil. The byproducts may be used for heating purposes.

Trade Names. 2-Ethylhexanol is usually marketed by the manufacturers (e.g., Ruhrchemie, BASF, Hüls, Union Carbide, Mitsubishi Chemical) under its chemical designation 2-ethyl-1-hexanol or as octyl alcohol. Typical *specifications* have been compiled in Table 3.

Table 3. Quality specifications for 2-ethylhexanol [3], [32]

Specification	Value
2-Ethylhexanol	≥99.5 wt %
Density at 20 °C	0.832 – 0.833 kg/L
Refractive index, n_D^{20}	1.431 – 1.432
Color, Pt – Co scale	max. 5
Distillation range (95 vol %) at 101.3 kPa	184 – 185 °C
Water content	max. 0.05 wt %
Pour point	< −60 °C

Storage and Transportation. Safety precautions for the shipment and storage of 2-ethylhexanol are determined by its combustibility, flash point, and ignition temperature (see Table 4). Dry 2-ethylhexanol does not corrode standard metals and, like other alcohols, can be stored in standard steel containers (e.g., ST 37). For particularly high-quality demands, use of stainless steel or aluminum containers is advisable. To prevent the entry of atmospheric oxygen or moisture, an inert gas cover should be provided. 2-Ethylhexanol can be transported in iron drums, tank trucks, or railway cars made of standard steel, aluminum, or stainless steel. Centrifugal pumps conforming to chemical standards with simple rotating mechanical seals and polytetrafluoroethylene (PTFE) flange

seals have proved to be suitable for use with 2-ethylhexanol.

Table 4. Safety information for 2-ethylhexanol

Safety parameter	Value
Flash point, closed cup	75 °C
Ignition temperature	270 – 305 °C
Lower and upper explosive limits in air at 101.3 kPa	1.1 – 7.4 vol %
Hazard classification for transport	
CFR 49: 172.101, flammable liquid	
RID/ADR class 3, number 32 c	

4. Uses

In the United States, 2-ethylhexanol is mainly used in the form of its secondary products for the following applications [1]:

Plasticizers	70 %
2-Ethylhexanol acrylate	15 %
Cetane improvers and lubricant additives	9 %
Surfactants	3 %
Miscellaneous	3 %

Worldwide, 2-ethylhexanol esters have >60 % share of the poly(vinyl chloride) (PVC) plasticizers market. In the United States, bis(2-ethylhexyl) phthalate [*117-81-7*], di-2-ethylhexyl phthalate (DEHP), also called dioctyl phthalate (DOP), dominates (70 %); this is followed by bis(2-ethylhexyl) adipate [*103-23-1*], di-2-ethylhexyl adipate (DEHA), also called dioctyl adipate (DOA), (16 %), and tris(2-ethylhexyl) mellitate, trioctyl trimellitate (12 %). In Europe, DEHP's share of the market is even higher. The outstanding importance of DEHP is due to its favorable property combination as a plasticizer (good gelling properties, low volatility, high resistance to heat and water, and excellent electrical properties) (→ Plasticizers). Comprehensive investigations have been conducted on the toxicology and ecology of the widely used chemical DEHP during the last few years. The results have shown that its health and ecotoxicological risks are extremely low [33], [34].

The second large field of application is the production of 2-ethylhexyl acrylate [*103-11-7*], which is used to manufacture coating materials (especially emulsion paints), adhesives, printing inks, impregnating agents, and reactive diluent/cross-linking agents. 2-Ethylhexyl nitrate [*27247-96-7*] serves as a cetane number improver [35]. 2-Ethylhexyl phosphates are used as lubricating oil additives [36]. Antifoaming agents (cf. [37], [38]), dispersants (cf. [39]), and flotation agents [40] made from 2-ethylhexanol deserve special mention as surfactants. Other applications of 2-ethylhexanol include its use as a solvent, above all for polymerization catalysts (cf. [41]) and in extracting agents (cf. [42]).

5. Economic Aspects

Low production costs for butyraldehyde in modern large-scale plants and the lower price of propene as compared with ethylene mean that the oxo route for the manufacture of 2-ethylhexanol will continue to be given preference for economic reasons. As the 2-ethylhexanol manufacturers have their own oxo and hydrogenation capacities, the 1-butanol formed as a byproduct via the hydration of butyraldehyde is also used. In modern plants, ca. 860 kg of 2-ethylhexanol and ca. 18 kg of 1-butanol are obtained from 1000 kg of butyraldehyde. Other production processes will be able to survive in the long term only in countries where the necessary raw materials are economically available. Table 5 lists worldwide capacities.

Table 5. Worldwide capacities for 2-ethylhexanol

Country/region	Capacity, 10^3 t/a
Western Europe	770
(Federal Republic of Germany)	(550)
Eastern Europe	490
United States	240
Central and South America	150
Asia	480
Total	2130

6. Toxicology

Oral LD_{50} values of 2-ethylhexanol are ca. 2.0 g/kg [43] and 3.7 g/kg in rats [44]. Gross necropsy revealed evidence of gastrointestinal

irritation. In the rabbit eye, the undiluted material produces an erythema, swelling of the conjunctiva, lacrimation, and mucous secretion [45].

After skin contact in rabbits, 2-ethylhexanol is mildly irritating [43] if the patch is not closed; otherwise moderate skin irritation occurs [46]. The lowest published LD_{50} after dermal application is 2 g/kg in rabbits [43].

Mice, rats, and guinea pigs survived inhalation of a nearly saturated atmosphere (227 mL/m^3) over a period of 6 h [43]. Typical signs of intoxication were central nervous depression, dyspnea, and irritation of mucous membranes. Repeated inhalation of a maximum dose of 110 mg/m^3 by rats caused dystrophic changes in parenchymatous organs [47].

The cumulative oral toxicity seems to be low [45]. A total of 12.5 g/kg in the diet fed to rats over a period of 90 d affected the kidneys and the liver [46]. An amount of 2 mL/kg fed to rabbits for 10 d caused signs of local irritation and systemic toxicity [43]. Peroxisomes were induced with liver enlargement when rats were fed with dietary levels of 2 % 2-ethylhexanol for a period of 3 weeks [48].

In rabbits [49] and rats [50], 2-ethylhexanol is conjugated to glucuronic acid and eliminated via the urine, its main metabolite being 2-ethylhexanonylglucuronide. A small amount of the radioactively labeled material is oxidized and expired as CO_2. Only 2 % is excreted unchanged.

Neither the ACGIH, OSHA, nor DFG have set standards for exposure levels.

1. Introduction

An *explosion* is a physical or chemical phenomenon in which energy is released in a very short time, usually accompanied by formation and vigorous expansion of a very large amount of hot gas:

1) Mechanical explosions are caused by the sudden breaking of a vessel containing gas under pressure
2) Chemical explosions are caused by decomposition or very rapid reaction of a product or a mixture
3) Nuclear explosions are caused by fission or fusion of atomic nuclei

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a10_143

4) Electrical explosions are caused by sudden strong electrical currents that volatilize metal wire (exploding wire)

Only chemical explosions are treated in this article.

For an explosion to occur, the reaction must be exothermic; a large amount of gas must be produced by the chemical reaction and vaporization of products; and the reaction must propagate very fast. For example, gasoline in air burns at a rate of ca. 10^{-6} m/s; a solid propellant, at ca. 10^{-2} m/s; and an explosive detonates at a rate of ca. $10^3 - 10^4$ m/s (detonation velocity).

The two different modes of decomposition are deflagration and detonation. *Deflagration* exhibits two characteristics: 1) the combustion is very rapid (1 m/s up to a few hundred meters per second) and 2) the combustion rate increases with pressure and exceeds the speed of sound in the gaseous environment, but does not exceed the speed of sound in the burning solid. The materials are often powdered or granular, as with certain pyrotechnics and black powder. *Detonation* is chemically the same as deflagration, but is characterized by a shock wave formed within the decomposing product and transmitted perpendicularly to the decomposition surface at a very high velocity (several thousand meters per second) independent of the surrounding pressure (see Chap. 2).

Explosive substances can be divided into three classes. Members of the first class detonate accidentally under certain conditions. These are explosible substances, some of which are used in industry as catalysts (e.g., peroxides), dyes, and fertilizers. This class includes products or mixtures whose formation must be avoided or controlled, e.g., firedamp, or peroxides in ethers. In the second class are products normally used for their quick burning properties but which may detonate under some circumstances, e.g., pyrotechnic compositions, propellants, and some kinds of hunting powder. In the third class are substances intentionally detonated for various purposes.

For reasons of safety, acquaintance with the first group of materials is necessary. The second group is described elsewhere (→ Propellants; → Pyrotechnics). Pure substances and mixtures of the third class are described here.

The distinctions between these three classes are not clear-cut because most explosives burn smoothly if they are not confined. However, if some fine hunting powder burns under certain confined conditions, combustion may become detonation. Dry nitrocellulose fibers can easily detonate, but this tendency is significantly lower in the gelatinized form. Some compositions, such as mixtures of cyclotrimethylenetrinitramine (RDX) with a binder, can be used as a propellant, gunpowder, or high explosive, depending on the type of initiation.

The third class consists of primary and secondary explosives. *Primary explosives* (initiator explosives) detonate following weak external stimuli, such as percussion, friction, or electrical or light energy. *Secondary explosives* are much less sensitive to shock. However, they can detonate under a strong stimulus, such as a shock wave produced by a primary explosive, which may be reinforced by a booster composed of a more sensitive secondary explosive. The various secondary explosives are used militarily or industrially as shown in Figure 1.

Functions and Constraints. Explosives can be either pure substances or mixtures. They function in such systems as munitions, where they are a component of a complex firing system or as firing devices in quarries or metal forming equipment. With such systems, the ingredients must fulfill one or more functions, while meeting various constraints arising in manufacture or use. Therefore, tests that represent these functions and constraints are required.

When an explosive detonates, it generates a shock wave, which may initiate less sensitive explosives, cause destruction (shell fragments, blast effect, or depression effect), split rocks and soils, or cause formation of a detonation wave. A detonation wave of special geometry (hollow charge effect) may modify materials by very rapid generation of high pressure; for example, shaped charges, metal hardening, metal-powder compaction, or transformation of crystalline forms. A shock wave may be used to transmit signals, e.g., for safety devices or in seismic prospecting.

In general, constraints are related to safety, stability, compatibility with other elements of the system, vulnerability, toxicity, economics,

Figure 1. Differentiation of explosible materials

and, more recently, environmental and disposal problems [21].

History [1], [4], [87]. Explosives were probably first used in fireworks and incendiary devices. The admixture of saltpeter with combustible products such as coal and sulfur produced *black powder*, already known in China in the 4th century A.C., described in 808 A.C. by Qing-Xu-Zi, and used as a military gunpowder in a book published in 1044. The use in shells during the mongolian wars around 1270 and a severe explosion in a factory in 1280 were described. The first correct description of the phenomenon of shock waves in air seems to be in a book by the scientist Song-Ying-Xing in 1637. Around 1580 first descriptions in Europe are known (siege of Berg-op Zoom). However, the difficulties of initiation upon impact against the target were not overcome until 1820 when *fulminate caps* were developed. In the early 1600s, black powder was used for the first time to break up rocks in a mine in Bohemia. This technique spread throughout western Europe during the 1600s. Ammonium perchlorate was discovered in 1832.

The development of organic chemistry after 1830 led to new products, although their explosive properties were not always immediately recognized. These include nitrocellulose and nitroglycerin.

The very important contributions of Alfred Nobel (1833 – 1896) include the use of mercury fulminate for the initiation of explosives (1859 – 1861), the development of *dynamites* (1873), and the addition of 8 % nitrocellulose to nitroglycerin (blasting gelatine, 1876).

Many new products were developed between 1865 and 1910, such as nitrated explosives, mixtures in situ of an oxidizer and a fuel, explosives safe in the presence of firedamp, chlorate explosives, and liquid oxygen explosives. Organic nitro compounds for military uses included tetryl, trinitrophenol, and trinitrotoluene.

Between the two world wars, RDX, pentaerythritol tetranitrate (PETN), and lead azide were produced. After 1945 cyclotetramethylenetetranitramine (HMX), 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), and hexanitrostilbene (HNS) were developed (see Chap. 5), as well as "fuel – air explosives". Ammonium nitrate – fuel oil (ANFO) explosives and slurries were developed for industrial uses; some were improved by adding bubbles or micropores.

In the 1880s Berthelot described the phenomenon of *detonation.* About the same time the hollow-charge effect was discovered, and the foundations of the hydrodynamic theory of detonation were established. In 1906, the first accurate measurements of velocities of detonation were made. After World War II, the science of

detonation was further developed and perfected [17].

Recently, new explosive compositions of low vulnerability (LOVA = low vulnerability ammunitions) are being developed. Major efforts are being made to use predicted properties (e.g., density, ΔH_f, sensitivity, themal stability) to avoid unnecessary experiments [18–20], [94], [102].

2. Physical Properties and Chemical Reactions

2.1. Detonation

The detonation process needed for most uses is characterized by a shock wave that initiates chemical reactions as it propagates through the explosive charge. The shock wave and reaction zone have the same supersonic velocity; a fraction of the chemical energy is used to support the shock.

2.1.1. Ideal Detonation

A model of ideal detonation (ID) is shown in Figure 2, with steady flow to the end of the reaction zone.

Figure 2. Ideal detonation

Stationarity requires the plane corresponding to the end of the reactions to be locally sonic. This condition, termed the Chapman – Jouguet (CJ) condition [23], [24], yields the relation $D = u + c$

needed to solve the equations of conservation of flow (where D = detonation velocity, u = particle velocity, and c = sound velocity).

The structure of the reaction zone of the ID plane detonation can be ignored, and the mechanical and thermodynamic data can be calculated by solving equations between the nonreacted and fully reacted states. The description of the ideal detonation is given by the model [25–27] represented in Figure 3 by the $p-V$ plane (Fig. 3A) and the pressure p vs. distance x profile at a given instant of time (Fig. 3B). This model relates the explosive at rest (V_0), the shocked nonreacted explosive (ZND spike ($*$)), and the end of the reaction zone (CJ plane ($\hat{}$)). This model has been recently experimentally ascertained by tests made by F. Bauer [28] with a PVDF piezogauge in cooperation with Lynn Barker by a VISAR system on a mixture PETN-binder.

Figure 3. Development of the ideal detonation
A) The $p-V$ plane; B) The pressure vs. distance profile; p pressure; V specific volume; D detonation velocity; H_0 Hugoniot curve of nonreacted explosives; H Hugoniot curve of reaction products; (0) explosive at rest; (1) reaction zone of length a, an arbitrary quantity; (2) isentropic release of the detonation product

In Figure 3A the three states are located on a straight line (Rayleigh line), with slope equal to $-D^2/V_0^2$.

The loci of the shocked states are termed Hugoniot curves: H_0 for the unreacted explosives, and H for the completely reacted explosives.

Some relations at the CJ plane can be expressed as a function of D and the polytropic coefficent of the detonation products:

$$\Gamma = \left(\frac{\partial \log \hat{\varrho}}{\partial \log \hat{V}}\right)_s$$

The notation $(\,)_s$ represents the derivative along the isentrope at the CJ point.

$$\hat{u} = \frac{D}{\Gamma+1} \quad \hat{p} = \varrho_0 \frac{D^2}{\Gamma+1}$$
$$\hat{c} = \frac{\Gamma}{\Gamma+1} D \quad \hat{\varrho} = \varrho_0 \frac{\Gamma+1}{\Gamma}$$

where ϱ = density These relations are valid for most condensed organic explosives $\Gamma \approx 3$, with the assumptions that $p_0 = 0$ and $u_0 = 0$.

2.1.2. Deflagration and Detonation

In a thermodynamic diagram such as Figure 3A, there is another point that satisfies the Chapman – Jouguet condition in the region $p < p_0$ (not drawn in the figure). It represents the Chapman – Jouguet deflagration, in contrast to the detonation:

Detonation	Deflagration
$\hat{p} > p_0$	$\hat{p} < p_0$
$\hat{u} > 0$	$\hat{u} < 0$
$\hat{V} < V_0$	$\hat{V} > V_0$

Unlike the detonation wave, the deflagration wave is subsonic, and consequently a precursor shock is propagated in front of the reaction zone. Its intensity and velocity depend on the chemical energy released and on the boundary conditions; in contrast to detonation, a specific explosive does not provide a unique solution for deflagration.

A precursor shock that is strong enough can, in addition to compressing the explosive, also heat it sufficiently to initiate reactions just behind its front; a progressive buildup of a completely stationary process identical with the ZND model of the detonation is observed. Consequently, a detonation is equivalent to a shock followed by a deflagration.

2.2. Prediction of Detonation Data

2.2.1. Complete Calculation [29]

The quantities D, $\hat{p}$, $\hat{u}$, $\hat{V}$, and $\hat{T}$ in the Chapman – Jouguet state are needed to evaluate further the effectiveness of the explosive on the surroundings in a given action. The calculation of these quantities requires the equation of decomposition, the heats of reaction, and an equation of state for the reaction products, which may be theoretical (virial expansion) [30], [31], semiempirical [32], empirical [33], or a constant Γ law. In addition, the equilibrium constants for the reaction given as a function of V and T are needed.

For organic explosives, the distinction between oxygen-positive or weakly oxygen-negative explosives, which give only gaseous products, and the strongly oxygen-negative explosives, which also give free carbon, is important. In fact, the assignment to one class or the other is determined by the values of the equilibrium constants for $(\hat{V},\hat{T})$ determined after a first calculation.

Inasmuch as $(\hat{V},\hat{T})$ are a function of the loading density ϱ_0, some explosives, for instance, pentaerythritol tetranitrate (PETN), produce free carbon at high loading densities and only gaseous products at moderate values of ϱ_0. Because of the complexity of the calculation, the number and formulation of the equations depend on the final result.

The thermochemical equations are solved with *a priori* (V,T) pairs to give gas product composition. The mechanical equations are then applied at the Chapman – Jouguet plane with the geometric condition represented on Figure 3A: at the CJ point, the isentropic and the Hugoniot curves have the same tangent, with a slope equal to $-D^2/V_0^2$.

2.2.2. Approximation Methods

A first prediction of the CJ data can be given by using methods valid for condensed explosives.

Chemical Potential. For many organic explosives, D and $\hat{p}$ can be expressed simply as a function of a parameter Φ defined as [34]:

$$\Phi = N\sqrt{\bar{M}_r Q}$$

N = number of moles of gaseous products per gram

$\bar{M}_r$ = average molecular mass of these products, g/mol

Q = enthalpy of the explosive minus the enthalpy of the products, J/g

The calculation of Φ is made under the assumption that:

$$\mathrm{O + H \longrightarrow H_2O}$$
$$\mathrm{O + C \longrightarrow CO_2}$$

i.e., the formation of water is considered before the formation of carbon oxides.

The following relations are then proposed:

$$D = A\,(1 + B\,\varrho_0)\sqrt{\Phi}$$
$$\hat{p} = K\,\varrho_0^2\,\Phi$$

A good fit with experimental data is found for organic explosives by setting

Figure 4. Sequence of reactions: explosive and combustible additive
a) Cast organic explosive; b) Aluminum grains or flakes

Figure 5. Sequence of reactions: explosive and oxygen-rich binder
a) Negative-oxygen-balance explosive; b) Oxygen-containing binder

$$A = 1.01 \quad B = 1.3 \quad K = 15.58$$

This method, which requires only a knowledge of the equation of decomposition, is useful for comparing organic explosives.

Rothstein Method. An empirical correlation has been found between the detonation velocity D and a parameter F, which is a function of the explosive molecule [35].

$$D(\varrho_0) = \frac{F - 0.26}{0.55} - 3(\varrho_{\mathrm{TM}} - \varrho_0)$$

ϱ_{TM} = theoretical density This correlation applies to both organic nitro and fluorinated nitro explosives.

$$F = 100\,\frac{n(\mathrm{O}) + n(\mathrm{N}) + n(\mathrm{F}) - \left(\frac{n(\mathrm{H}) - n(\mathrm{HF})}{2n(\mathrm{O})}\right)^{*}}{M_{\mathrm{r}}} + 100\,\frac{\frac{A}{3} - \frac{n(\mathrm{B/F})}{1.75} - \frac{n(\mathrm{C})}{2.5} - \frac{n(\mathrm{D})}{4} - \frac{n(\mathrm{E})}{5}}{M_{\mathrm{r}}} - G$$

where n(F), n(HF), and n(B/F) are the elemental terms for fluorinated explosives, and where $G = 0.4$ for each liquid explosive component, $G = 0$ for solid explosives, and $A = 1$ if the compound is aromatic; otherwise $A = 0$.

$*$ If $n(\mathrm{O}) = 0$ or if $n(\mathrm{HF}) > n(\mathrm{H})$, this term = 0.

For 1 mol of composition:

n(O) = number of oxygen atoms
n(N) = number of nitrogen atoms
n(H) = number of hydrogen atoms
n(F) = number of fluorine atoms
n(HF) = number of hydrogen fluoride molecules that can form from available hydrogen
n(B/F) = number of oxygen atoms in excess of those available to form CO_2 and H_2O or the number of fluorine atoms in excess of those available to form HF
n(C) = number of oxygen atoms doubly bonded to carbon as in a ketone or ester
n(D) = number of oxygen atoms singly bonded to carbon as in C–O–R where R = H, NH_4, C, etc.
n(E) = number of nitrato groups existing as a nitrate ester or as a nitric acid salt such as hydrazine mononitrate

Molecular masses and atomic composition for explosive mixtures must be derived as sums of mass-average molecular mass and of elemental mole fractions. The prediction of the detonation velocity is ca. 95 % accurate.

2.3. Nonideal Detonation Waves and Explosives

A detonation wave is nonideal if the geometry and dimensions of the charge are such that the reaction zone is affected by lateral shock or rarefaction waves. Consequently, the nonideality depends strongly on the dimensions of the charge and the explosive composition characterized by a given reaction zone length.

An explosive composition consisting of components with different reaction kinetics does not satisfy the ideal detonation model, which assumes all the exoenergetic reactions to be completed simultaneously in the sonic Chapman–Jouguet plane. Such compositions are nonideal explosives. The ideal detonation model applies only as an approximation to most multicomponent explosives; however, with data on reaction kinetics under pressure often lacking, calculations are commonly based on the ideal detonation model.

2.3.1. Nonideal Explosive Compositions

An example of an organic explosive with a metallic nonexplosive additive is a dispersion of aluminum grains or flakes in a cast organic explosive. The process sequence is shown in Figure 4. The energy effectively supporting the detonation wave has been delivered at time t_A. The absorption of energy by aluminum reduces $\hat{p}$ and D, but the late combustion of the aluminum allows the pressure to be sustained behind the CJ plane, thereby increasing the total impulse transmitted to the surroundings.

The possible sequence of an organic explosive (a) with a negative oxygen balance cast or pressed with a binder containing oxygen (b) is shown in Figure 5. The relatively slow decomposition of the binder produces oxygen gas, which shifts the reaction of the organic explosive toward better oxygen balance, thus increasing energy production.

A typical example of a mixture of two explosive components with different reaction kinetics is a mixture of trinitrotoluene (TNT) and ammonium nitrate (AN). The slower reaction of AN produces energy and an excess of oxygen, which shifts the equilibrium of the TNT reaction to a higher energy release. Because the detonation of the nonideal explosives involves heat transfer between components, the specific surface areas become important. Moreover, because the total reaction zone is relatively long, detonation depends on the dimensions of the charges.

2.3.2. Detonation of Cylindrical Cartridges

In the detonation of cylindrical cartridges, the reactive flow is two-dimensional, stationary, and relatively easy to model. Many military or engineering applications use cylindrical geometry.

The basic phenomenon is the interaction of the inwardly propagating rarefaction fan, originating at the outer surface as it is reached by the shock wave, with the reaction zone. The first consequence of this interaction is freezing of the reactions by cooling, which reduces the released energy. A second effect is a curvature of the detonation front and a loss in energy through a diverging flow. The reaction zone length and the radius of the cartridge are two quantities that play opposite roles in the process.

The experimental determination of the detonation velocity as a function of the diameter produces a curve limited in two ways:

1) As the diameter increases, the detonation velocity D approaches a constant value D_i equal to that of the ideal detonation wave.
2) Below a given diameter d, called the critical diameter, d_{cr}, the detonation is no longer self-supporting and fails.

Many analytical expressions $\frac{D}{D_i}(d)$ have been proposed in which the explosive is characterized by its ideal reaction zone length. The function $D(d)$ and the critical diameter d_{cr} depend on both the length and the structure of the reaction zone, i.e., on factors that affect this zone, such as the loading density ϱ_0, grain size g, initial temperature t_0, and composition, especially in the case of mixtures.

As an example of the effects of these factors on ideal explosive compositions, the influence of ϱ_0 is shown in Figure 6 for the conventional military composition 60 RDX/40 TNT (composition B) [36]. In the case of energy-rich explosives, the effect of the cylinder diameter increases with decreasing density, whereas the critical diameter decreases with increasing density and increasing

temperature [37]. The influence of mean grain size, e.g., that of powdered TNT, is shown in Figure 7 [29], and most nonideal explosive compositions and some pure explosives exhibit a particular behavior (see Chap. 6).

Figure 6. Detonation velocity D vs. diameter d for two densities ϱ of 60 wt % RDX – 40 wt % TNT

Figure 7. Detonation velocity D vs. diameter d for several grain sizes g of powered TNT

2.3.3. Low- and High-Order Detonation Velocity

Some explosives exhibit two different detonation velocities, depending on the diameter of the cartridge and the initial ignition energy. Such explosives always have a relatively low energy and loading density, with great sensitivity to shock waves [36]. Conventional examples are the dynamites and highly porous explosives [38].

The high sensitivity to shock waves tends to allow the detonation to be sustained. This is true even when the development of the reactions is seriously limited by the size of the cartridge. Thus, under steady conditions, a state of shock plus reaction would correspond to that appearing in a transient regime in the buildup of heterogeneous explosives to detonation.

2.3.4. The Effect of Confinement

Confinement usually delays the arrival of the expansion waves on the axis. A confined charge is equivalent to a charge having a large diameter. However, two anomalous effects should be noted: if the velocity of sound in the confinement exceeds the detonation velocity for the given diameter, a foreshock is propagated ahead of the wave. This foreshock can accelerate the wave (increase the density) or stop the detonation, i.e., desensitize a porous explosive by compaction, the explosive becoming homogeneous. An analogous desensitizing effect can be generated if there is an air gap between the explosive and the container. The expanding reaction products adiabatically compress the porous explosive. This effect can stop the detonation of mining charges embedded in boreholes.

2.4. The Buildup of Detonation

2.4.1. Combustion – Deflagration – Detonation Transition (DDT)

Deflagration can generate a shock wave, which is propagated in the unreacted medium, and if strong enough, can initiate reactions and become a detonation wave. This transition can occur only if the explosive charge is confined or is of such a size that expansion waves do not prevent formation of a shock wave. Accident reports have shown that DDT affects a variety of explosives and propellant charges.

However, different phenomena, which depend on the mechanical properties of the medium, may occur [39], [40]: if the explosive is porous or exhibits poor mechanical behavior, the gas formed and subjected to pressure is injected between the grains or into cracks, increasing the combustion surface. The resulting acceleration stops only when detonation occurs. The path versus time of the observed ionization front is continuous. In the case of explosives stiff

enough to withstand an elastic wave, a steady deflagration develops as soon as the pressure makes the medium impervious to the gas. The transition to detonation occurs as the pressure of the gas formed behind the deflagration zone becomes high enough to generate a shock wave. Detonation occurs when the shock wave reaches the front of the deflagration wave. As a consequence, a discontinuity is observed in the path versus time of the ionization front.

2.4.2. Shock-to-Detonation Transition (SDT)

If the end of an explosive charge is subjected to a shock wave, the steady detonation appears only at a distance s and with a delay τ inside the explosive charge [41]. For a given composition, s and τ are inversely proportional to the intensity of the shock wave. There are two SDT processes: one for homogeneous (for instance, a liquid) and one for heterogeneous composition.

Homogeneous Explosives. The shock wave (a) in Figure 8 propagated at constant velocity initiates decomposition reactions that are first completed along the entrance side (b) at time τ, the detonation appearing at point A. The detonation wave (c) travels in a compressed medium heated by shock wave (a). Therefore, the detonation wave (c) travels with a velocity exceeding the normal detonation velocity, which is attained at point B (wave d) as soon as wave c has reached wave a.

Figure 8. Detonation buildup (SDT), homogeneous explosive

Heterogeneous Explosives. In Figure 9, the shock wave (a) is gradually accelerated by the energy released upon its passage. Its acceleration ends with the appearence of a detonation wave at point B. This wave is characterized by its luminosity, as seen on optical records. Sometimes a second wave starts from point B and moves backward in the explosive, which has reacted only partially (retonation wave). The macroscopic analysis can be explained by the microscopic heterogeneities of the explosive [42].

Figure 9. Detonation buildup (SDT), heterogeneous explosive

The energy of the shock wave is converted into heat energy by the implosion of occluded gas bubbles, the impact of microjets, or the adiabatic shearing of the powder grains. All the observations allow for two successive phases, ignition and buildup, that are accomodated by numerical models assuming inward or outward combustion of the grains [43].

2.4.3. Shock and Impact Sensitivity

The sensitivity of the explosives to an applied load is measured by the maximum load at which no detonation occurs, or at which there is a 50 % occurrence of detonation, i.e., a 50 % chance of failure. The sensitivity to shock loading depends on the pressure p^* and its action time τ^*. Sensitivity is defined with the aid of the curve p^* (τ^*), which separates detonation points from failure points.

For a variety of explosives and for a certain pressure range, the sensitivity is defined by the relation $(p^*)^2 \tau^* = \varepsilon$, where ε is a constant that depends on the composition and exhibits the dimension surface energy per unit area [44].

Figure 10. Initiation energy threshold vs. shock pressure a, b) HMX plus binder; c, d) Cast RDX compositions

Figure 10 shows that the concept of the energy threshold is an acceptable approximation for solid-state compositions [45]. For liquid explosives, which exhibit different behavior, the relation $\tau*$ ($p*$), based on an Arrhenius-type kinetic theory (with initial temperature $T*$ expressed as a function of pressure $p*$) accurately reproduces the experimental findings. The critical time $\tau*$ is equal, for a given shock pressure, to the time of the shock-to-detonation transition (see Fig. 8). Except for primary explosives, the sensitivity to shock-wave action and the shock-to-detonation transition are both dependent on the homogeneity of the composition. Sensitivity is affected by grain size [103] and internal grain defects [104]. The reaction of an explosive to impact loading depends on several factors. If the projectile is a large plate, the reaction is identical with that observed in the preceding case: the shock wave induced by the impact depends on the velocity and acoustic impedance, whereas the action time is proportional to the plate thickness. In tests of sensitivity to shock-wave action, the impacting plates are driven by explosives. If the projectile is a small sphere or cylinder, the interaction with the target becomes complex [41]. If the shock wave cannot induce a shock–detonation transition, it degenerates into an adiabatic compression. Frictional and shearing effects can cause ignition. Finally, a phenomenon analogous to the deflagration–detonation transition (see Section 2.4.1) is observed, in which the mechanical properties of the explosive play a part.

2.5. Classification of Explosives

For many years the behavior of cylindrical cartridges, as described in Section 2.3.2, was regarded as typical of ideal explosives. A detailed analysis has shown, however, that classification of explosives into two groups is possible, taking into account the influence of the loading density ϱ_0 on the detonation velocity as a function of the cartridge diameter and the critical diameter [46].

Figure 11. Detonation behavior of ammonium perchlorate; η = percent of the theoretical maximum density

The first group includes a variety of organic explosives: TNT, RDX, HMX, and their mixtures (see Chap. 5). The second group includes mixtures of an explosive and a combustible nonexploding constituent (nonideal composition). This group also includes some pure explosives such as hydrazine mononitrate (HN), nitroguanidine (NG), ammonium nitrate (AN), dinitrotoluene (DNT), dinitrophenol (DNP), and ammonium perchlorate (AP). The behavior of the second group is illustrated for ammonium perchlorate in Figure 11.

2.6. Functional Groups

Certain groups impart explosive potential.

2.6.1. Nitro Group

The nitro group is present in the form of salts of nitric acid, ONO_2 derivatives (nitrate esters), CNO_2 derivatives (aliphatic or aromatic nitro compounds), and NNO_2 derivatives (*N*-nitro compounds such as nitramines, nitroureas, etc.).

Salts of Nitric Acid. Salts of nitric acid include the alkali metal and alkaline earth metal nitrates, ammonium nitrate, and the nitrates of methylamine, urea, and guanidine. These are usually low-density, water-soluble, sometimes hygroscopic compounds. With the exception of some salts of hydrazines, e.g., triaminoguanidine and hydrazine nitrates, they are insensitive to impact and friction.

***O*-Nitro Derivatives, Nitrate Esters ($RONO_2$).** The low molecular mass representatives are liquids or low-melting solids. They are sensitive to impact when the number of carbon atoms and $-ONO_2$ groups are equal or nearly equal. Densities are in the medium range, except for symmetrical molecules such as pentaerythritol tetranitrate (PETN). Heat stability is moderate; they are subject to hydrolysis and autocatalytic decomposition.

***C*-Nitro Derivatives (CNO_2).** Aliphatic and cycloaliphatic nitro compounds differ greatly from the aromatic and heteroaromatic series. Members of the first group have limited explosive properties, except when the number of NO_2 groups equals or exceeds the number of carbon atoms, as in some *gem*-dinitro compounds and derivatives of nitroform, $HC(NO_2)_3$. The latter are often shock sensitive, with limited heat stability. The compounds $RCF(NO_2)_2$ are stable to heat and rather insensitive [6], [7]. Members of the second group containing two or three NO_2 groups per ring are valuable; they are often dense and insensitive to impact, with good hydrolytic and thermal stability.

***N*-Nitro Derivatives (NNO_2).** *N*-Nitro derivatives are often difficult to synthesize. They exhibit high densities and detonation velocities, with some sensitivity to impact. RDX and HMX are representative.

2.6.2. Other Groups

Organic chlorates and perchlorates, peroxides, metal salts of some organic compounds (acetylides and nitronates), and some organic compounds with three-membered rings or chains of nitrogen atoms or triple bonds have only limited application, except as primary explosives. Most are very dangerous to handle.

Nitroso (NO) compounds are usually unstable. So-called hexanitrosobenzene is an exception; however, it is actually not a nitroso compound but a furoxan derivative (benzotrifuroxan). It is of interest because it is free of hydrogen (zero-hydrogen explosive). Other furoxanes and also furazanes have explosive properties [88].

The difluoroamine group imparts explosive character, increased density and volatility, a lower melting point and detonation velocity, and often much higher impact sensitivity. These compounds resemble primary explosives.

Many metal azides are primary explosives. Some organic azido derivatives are being studied because of their high density and stability. However, polyazido compounds can be very sensitive.

3. Application

3.1. Energy Transfer from the Explosive to the Surroundings

The energy available in the gaseous reaction products is transferred to the surroundings by shock waves. The mechanical effects depend on the geometry of the charge and the surroundings, on the distance from the charge, and on the acoustic impedance of the media. The explosive energy is used either to create compression and tension for engineering applications or to accelerate projectiles for military applications.

3.1.1. Shock and Blast Waves

The highest dynamic pressures are produced at the exit end of the charge, where the detonation shock is transferred to the inert material. The shock pressure is a function of the shock impedance. It is defined by the so-called shock polar curve of the pressure (p) vs. particle velocity (u). By a graphical method (Fig. 12) the induced pressure can be determined at the intersection of a shock polar curve with the detonation gas-product curve passing through the CJ point.

Figure 12. Determination of shock pressure p and particle velocity u induced in an inert material by an explosive; PMMA = poly(methyl methacrylate)

Even higher pressures can be obtained by using converging geometries or, indirectly, by a two-stage device. The explosive accelerates a thin metal plate, which generates an intense shock in the solid specimen as it strikes it in free flight. During wave propagation in the surrounding medium, the intensity of a shock wave decreases and the pressure profile changes. At a given distance from the charge, compression alternates with tension. The mechanical effects are a function of the maximum pressure and of the positive and negative impulses comprising the so-called blast wave. The maximum and minimum pressures are represented in Figure 13 as a function of the reduced distance $R/m^{1/3}$ from the charge.

Figure 13. Front pressure p_f and minimum pressure p_{min} in air vs. reduced distance $R/m^{1/3}$ from TNT in air, where R is the distance in meters and m the mass in kilograms

3.1.2. Casing and Liner Acceleration

A casing or liner in contact with an explosive charge is accelerated by a three-step process:

1) u_1 given by the shock wave
2) $u_2 \approx 2\,u_1$ given by reflection of the shock wave in a release wave at the free surface
3) u_3 given by the further expansion of the gaseous detonation products

The Gurney formula gives an approximate u_3 for a casing filled with an explosive characterized by the quantity E, which is given in J/kg [47]:

$$u_3\,(\mathrm{m/s}) = (2E)^{1/2}\left(\frac{M}{C}+\alpha\right)^{-1/2}$$

where

M = mass of the casing, kg
C = mass of the explosive, kg
$\alpha = 0.5$ for a cylindrical charge and
$\alpha = 0.6$ for a spherical charge

3.2. High Compression of Solids

Explosives provide the most powerful means for compressing solids in spite of the fact that at high pressure the heating limits the volume reduction.

Production of New Crystal Phases. The large pressure generated by shock waves may be used to transform one crystal phase into another (polymorphic transformation). The best known example of this technique is the transformation of graphite into diamond. Unfortunately, the short duration of the shock limits this technique to the production of small crystals used as abrasives.

Powder Compaction. The compression of powders by shock waves produced by explosives creates high pressures and temperatures simultaneously, resulting in grain welding. The main problem, which has been solved only recently, is the explosion caused by the interaction of release waves, which follow the shock; special geometries are required [48]. Rapidly solidified amorphous and metastable microcrystalline materials and ultrahigh-strength ceramics are expected to be produced by this technique.

Shock Hardening. The detonation of a thin sheet of explosive covering a piece of steel creates great surface hardness by a sequence of rapid compression, heating, and cooling.

Figure 14. Setups for metal forming
A) Free forming; B) Bulkhead forming

3.3. Metal Forming and Welding

The detonation of an explosive charge is used to form a metal plate; the shock wave is moderated by a liquid transmitting medium (Fig. 14). Techniques of free forming (Fig. 14A) or bulkhead forming (Fig. 14B) may be used.

A grazing detonation may weld two metal plates with diffusion of metal through the interface (Fig. 15) [49]. The required collision velocity, v_c, depends on the materials. This process is called explosive welding or cladding.

Figure 15. Explosive welding or cladding

3.4. Rock Blasting [36]

In rock blasting the charges are placed in drill holes, which are usually parallel to the rock surface. With strong confinement, most of the explosive energy is usefully employed, even though much of it is released by afterburning. Equally good results are given by nitroglycerin in high (6000 – 8000 m/s) or low (2000 – 3000 m/s) explosives. Various types of wedge cuts are used for tunnel blasting.

3.5. Perforators, Shaped or Hollow Charges

An explosive can be used to produce a thin, high-speed metallic projectile capable of perforating armor [50]. Nonmilitary applications include oil recovery.

A cavity in the explosive (Fig. 16) is lined with a metal, usually copper. The detonation divides the liner into two parts that move along

the axis at different velocities. Most of the mass of the liner forms the so-called slug at a velocity of several hundred meters per second. The remainder forms a thin projectile which is elongated because of the difference of velocity between the first formed elements near the apex (u_{jet} max. $\approx 8000-11\,000$ m/s) and those formed last (u_{jet} min. $= 1500-2000$ m/s). The ultimate length of the projectile depends on the ductility of the liner and can be > 10 times the diameter of the charge.

Figure 16. Projectile formation

When the projectile strikes a solid or liquid target, it drills a deep, narrow hole. The hole depth P is given approximately by the expression

$$P = L\sqrt{\frac{\varrho_{\mathrm{j}}}{\varrho_{\mathrm{t}}}}$$

where L is the length of the projectile and ϱ_{j} and ϱ_{t} are the densities of the projectile and target.

4. Primary Explosives

Under low-intensity stimulus of short duration, primary explosives, even in thin layers, decompose and produce a detonation wave; the activation energy is low. The stimulus may be shock, friction, an electric spark, or sudden heating. The deflagration – detonation transition occurs within a distance often too short to be measured. The released energy and the detonation velocity of primary explosives are small. Their formation is often endothermic.

The main function of primary explosives is to produce a shock wave when the explosive is stimulated by percussion, electrically, or optically (laser), thus initiating a secondary explosive. Primary explosives are the active detonator ingredients. Some are used in primer mixtures to ignite propellants or pyrotechnics. Because of their sensitivity, primary explosives are used in quantities limited to a few grams, and are manufactured under special precautions to avoid any shock or spark. To be used in industry, primary explosives must have limited sensitivity and adequate stability to heat, hydrolysis, and storage. Mercury fulminate, azides, and diazodinitrophenol are among the few products that meet these requirements and that can detonate a secondary explosive. Others, e.g., lead styphnate or tetrazene, initiate burning or act as sensitizers.

Properties of primary explosives are given in Table 1.

Mercury fulminate [*628-86-4*], $Hg(ONC)_2$, M_{r} 284.65, was first prepared in the 1600s and was used by Nobel in 1867 to detonate dynamites. It is prepared by the reaction of mercury with nitric acid and 95 % ethanol, in small quantities because the reaction is difficult to control. Mercury fulminate is a gray toxic powder, which lacks the stability for storage. It reacts with metals in a moist atmosphere; in most industrial countries its use has been abandoned.

Lead azide [*13424-46-9*], $Pb(N_3)_2$, M_{r} 291.26, discovered by Curtius (1891) [13], was developed after World War I and is now an important primary explosive. It is produced continuously by the reaction of lead nitrate or acetate with sodium azide in aqueous solution under basic conditions to avoid formation of hydrazoic acid, which explodes readily. The crystal size must be carefully controlled, large crystals being dangerous, by controlling the stirring and by using wetting agents. Demineralized water must be used. With thickeners such as dextrin, sodium carboxymethylcellulose, or poly(vinyl alcohol), purities from 92 % to 99 % are possible, the former containing 3 % dextrin and 4 – 5 % $Pb(OH)_2$. The lower sensitivity of the 92 % lead azide to impact and friction compared to purer lead azides facilitates detonator loading. Lead azide has good stability to heat and storage. Contact with copper must be avoided because *copper azide* is extremely sensitive;

Table 1. Properties of primary explosives

Property	Lead azide, pure	Silver azide	DDNP	Lead styphnate	Tetrazene

∗ Theoretical. ∗∗ After 5 s.

aluminum is preferred. *Silver azide* is used at high temperature or in miniaturized pyrotechnic devices. It is prepared from aqueous silver nitrate and sodium azide.

Diazodinitrophenol [*28655-69-8*], DDNP, $C_6H_2N_4O_5$, M_r 210.06, is obtained by diazotizing picramic acid and purified by recrystallization from acetone. It is sparingly soluble in water, nonhygroscopic, and sensitive to impact, but not as sensitive to friction or electrostatic energy. It is less stable to heat than lead azide. It is most often used in the United States.

Lead styphnate [*15245-44-0*], lead trinitroresorcinate, $C_6HN_3O_8Pb$, M_r 450.27, is produced continuously by the aqueous reaction of the magnesium salt with lead acetate, sometimes in the presence of agents that promote the formation of the correct crystalline form. Especially sensitive to electrostatic discharge, it is most frequently used to sensitize lead azide and in primer compositions to initiate burning.

Tetrazene [*31330-63-9*], $C_2H_8N_{10}O$, M_r 188.07, is obtained by the reaction of sodium nitrite with a soluble salt of aminoguanidine in acetic acid at 30 – 40 °C. It decomposes in boiling water. Its greatest value is for the sensitization of priming compositions.

Now it is a trend in research of new primary explosives in order to replace the compounds containing lead (environmental problem).

5. Secondary Explosives

5.1. Production

Common high explosives are usually made by liquid-phase nitration. The overall mechanism is believed to be ionic, with NO_2^+ generally the reactive species. In some cases, N_2O_4 may be added to a double bond or to an epoxy group. It is also possible to nitrate gas-phase hydrocarbons. The most important nitrating agent is nitric acid → Nitric Acid, Nitrous Acid, and Nitrogen Oxides.

Numerous end products of nitration are soluble in concentrated HNO_3, and may be recovered by dilution. However, dilution below ca. 55 wt % acid is not economic.

To increase the NO_2^+ content (3 wt % in pure HNO_3), lower the solubility of end products, reduce oxidative side reactions, and facilitate the treatment of spent acids, mixtures of sulfuric and nitric acids (mixed acid) are used. The water content of a mixed acid may be reduced by adding oleum. In 50: 50 wt % mixed acid, the nitric acid is ca. 15 % dissociated.

However, sulfuric acid is difficult to remove from products by washing. Furthermore, some substances (e.g., nitramines, nitriles, etc.) are decomposed. Orthophosphoric acid or polyphosphoric acid may be used instead of sulfuric acid;

however, these phosphoric acids are more expensive and more difficult to recover.

Mild nitration or nitrolysis can be conducted in mixtures of nitric acid and acetic anhydride or acetic acid; the reactive species may be $CH_3COONO_2H^+$. Mixtures of nitric acid and acetic anhydride containing between 30 and 80 wt % HNO_3 can detonate [51]. A high concentration of acetic anhydride avoids this danger. More recent nitration methods use N_2O_5 as a solution in pure nitric acid ("nitric oleum") or in chlorinated solvents (e.g., CH_2Cl_2). Three processes for the production of nitric oleum are in operation or in development [90]:

1) Oxidative electrolysis of a $N_2O_4 - HNO_3$ mixture
2) Ozonation of N_2O_4
3) Distillation of an oleum $(H_2SO_4 + SO_3) - NH_4NO_3$ mixture [89]

Nitric oleum allows yields to be improved and permits some syntheses to be performed that are not possible by other routes; the organic N_2O_5 solutions allow nitration to be performed under very mild and selective conditions [16], [90]. These nitrating agents must be used at their site of production.

Nitration. Reaction is exothermic. Dilution of the nitric and mixed acids with water liberates heat [52]. Normally, nitration is rapid. However, 70 – 85 wt % nitric acid is also an oxidant, and for this reason the reaction is best conducted continuously to limit the contact time of the product with the reactive medium. If the medium is free of solid particles, a tubular reactor can be used; otherwise, reactors in cascade with efficient stirring are employed. These reactors are made of highly polished stainless steel. Reactors and stirrers must be carefully designed to avoid dead zones and friction with crusts of explosives. Reactors are often provided with a valve that opens quickly to discharge reactants into a dilution vessel in an emergency.

Product Isolation. If a precipitate is not highly sensitive to friction, it may be centrifuged. For safe continuous filtration, the product must be stable in its mother liquor, and the filter design must avoid introduction of the explosive between moving and fixed parts. The precipitate is washed in two stages. The first uses only a small amount of water, which is recovered and mixed with spent acid. The acid is recovered from this mixture.

Purification. Treatment with boiling water is sometimes sufficient to hydrolyze impurities and wash out nitric acid. Crystallization eliminates sulfuric acid and produces the desired grain size. The solvent can be diluted with water or removed by steam distillation. Very fine crystals are obtained by dilution with high-speed stirring or by grinding in water or an inert liquid. A fluid energy mill may also be used. Size separation can be effected by sieving under flowing water or in a classifier. Drying is usually done as late as possible in the process.

Recovery of Spent Acids. Acid recovery in an explosive plant is of great importance in controlling production costs. These acids include 55 wt % HNO_3, 63 – 68 wt % H_2SO_4 from nitric acid concentration, and spent H_2SO_4 containing some nitric acid and nitration products.

To concentrate nitric acid, water is removed by countercurrent extraction with 92 – 95 % H_2SO_4. At the top, 98 – 99 % HNO_3 is produced. At the bottom, 63 – 68 % H_2SO_4 is obtained, which can be concentrated to 93 % by stripping with combustion gases, or to 96 – 98 % by vacuum distillation. Nitric acid can also be concentrated by distillation over magnesium nitrate.

Sulfuric acid is freed of nitric acid and nitro compounds by heating or steam injection.

Pollution Problems. Gaseous pollution may occur during nitrations, with evolution of red nitrous fumes. These can be absorbed in columns by recycling water or dilute nitric acid to provide 50 – 55 wt % acid.

Liquid and solid pollution is created by washing. Usually acids are transferred to decanting and settling basins, where product and other solid particles settle and liquids are neutralized. Some liquid wastes require special treatment; for example, the red liquors from TNT are best destroyed by combustion.

Safety [9], [11]. Accidents caused by detonation are usually very severe. In addition to the normal precautions required in acid handling, the production and use of explosives obviously

involves special risks. Loss of life and destruction of property by an accidental explosion must be prevented at all costs, and the detonation of explosives stored near populated areas must be avoided. Minimum distances between plant and nearby structures are regulated.

The transmission of detonation by pipes or feeding devices must also be prevented by appropriate arrangements. The danger of detonation by an accidental fire can be mitigated by limiting vessel size. Detonations by shock and friction in pipes, pumps, or valves are prevented by suitable measures.

The following principles apply: partition of risks (e.g., specific buildings for specific operations); limitation of risks (limited number of persons present and limited quantities of explosives); and installation of two or three independent safety devices. Some of these measures are taken by the manufacturers under the supervision of professional organizations following government regulations.

5.2. Specific Secondary Explosives

Properties of secondary explosives are given in Tables 2 and 3.

Table 3. Impact sensitivity of secondary explosives *

Explosive	Value **

5.2.1. Nitrate Esters

Nitrate esters $RONO_2$ are prepared from alcohols and nitric acid, which may be mixed with sulfuric or acetic acid. The reaction is reversible:

$$NO_2^+ + ROH \rightleftharpoons RONO_2 + H^+$$

In an anhydrous medium the equilibrium shifts to the right; with dilution, hydrolysis occurs. In 60 – 80 % HNO_3, the unreacted alcohol may be oxidized. Furthermore, a catalytic effect of the nitrous acids produced causes rapid decomposition of the reaction medium. This decomposition either does not occur or occurs very slowly with an acid concentration below 55 %. Nitrate esters are usually less stable if traces of acid are present. Traces of sulfuric acid are difficult to remove from solid nitrate esters; therefore, mixed acid should not be used for their preparation. Acetic – nitric acid mixtures are used with sensitive or oxidizable alcohols.

Pentaerythritol tetranitrate [*78-11-5*], PETN, $C_5H_8O_{12}N_4$, M_r 316.15, is scarcely soluble in 82 % HNO_3 (0.7 wt %). The nitration of pentaerythritol is practically complete in a few seconds and is conducted continuously. Pentaerythritol and HNO_3 (ca. 1 : 5.5) are fed into a well-stirred, jacketed reactor, with overflow in cascade into a second reactor of the same design. The temperature is maintained below 30 °C. PETN precipitates and may be isolated in one of two ways:

1) In a third reactor the reaction mixture is diluted with water to 55 wt % acid (c_{PETN} = 0.1 wt %) and filtered. The PETN is washed with water
2) The reaction mixture is filtered immediately and then the 82 wt % spent nitric acid is concentrated, a cheaper process but less safe

Washed PETN is stable. It can be recrystallized by dilution of a hot acetone solution with water, which removes traces of acid and some organic impurities, and crystals of desirable size and flow properties for continuous feed purposes are obtained. Pentaerythritol tetranitrate is fairly stable above 100 °C and in alkaline medium. It is a powerful high explosive, with a small critical diameter, easy to initiate, and sensitive to impact and friction. But that sensitivity depends on the crystal size: PETN is more insensitive if ultrafine or in form of a very big monocrystal. Nanometric PETN was recently obtained by a sol – gel process. It is used in detonators, commercial detonating cord, boosters (with wax), sheet explosives (with an elastomeric binder),

and plastic explosives. In a mixture with TNT, it is employed in some warheads and in industrial explosives.

Nitroglycerin [*55-63-0*], NG, $C_3H_5O_9N_3$, M_r 227.09, unlike PETN, is a liquid at room temperature, totally miscible with HNO_3 of higher than 70 % concentration, sparingly soluble (3 wt %) in 50 % HNO_3, and sensitive to hydrolysis (any contact with hydrolytic medium must be very short) [53]. It is prepared by continuous two-phase nitration of glycerol in anhydrous mixed acid. The mass ratio of pure anhydrous glycerol ($H_2O < 0.5$ %) and 50: 50 mixed acid is 1: 5. The product is washed with aqueous sodium carbonate or bicarbonate.

In the Schmid–Meissner and Biazzi processes, the reactor is a vessel with overflow and good stirring and cooling. The reactants are fed continuously, while the temperature is kept at 10–20 °C. The emulsion produced flows into a separator, which in the Schmid process does not have moving parts. In the Biazzi process, the separator is conical with peripheral feeding, breaking the emulsion by rotation. The product is washed with alkaline water in columns (Schmid) or in mixer–settlers (Biazzi).

In the Gyttorp process, developed in the 1950s, the feeding of acid and alcohol can be interrupted simultaneously. The key feature is the use of an injector with an axial flow of acid; the alcohol is sucked through the neck with excellent mixing. For good suction and heat absorption, a volume ratio of acid: alcohol of ca. 8 is required; it is maintained by recycling part of the spent acid. The glycerol is heated to 48 °C to reduce viscosity. The emulsion that is formed is cooled to 15 °C, and centrifuged continuously to separate the nitroglycerin from spent acid. The product is emulsified with alkaline wash water by passage through an injector; it is separated and washed again until neutral. The final emulsion can be safely transmitted through pipes. The quantity of nitroglycerin present at any given time can be kept low, and safety is further increased by protective walls and the use of remote control.

Other liquid nitrates are produced by these processes; the Gyttorp process requires a liquid alcohol reactant. The spent acid may be purified by heating. Nitroglycerin is used in propellants, gunpowder, and dynamites.

5.2.2. Aromatic Nitro Compounds

The most common nitro-aromatic explosives contain the picryl (2,4,6-trinitrophenyl) group and are usually obtained by nitration. The Ingold mechanism involves nitronium ion, NO_2^+; electrophilic attack occurs with formation of a σ-complex intermediate [22].

The introduction of a second and third nitro group requires increasingly severe conditions, including more anhydrous mixed acids and elevated temperatures (above 100 °C for trinitration).

Some of these aromatic nitrocompounds are not used or are abandoned as explosives: among them:

1,3,5-Trinitrobenzene [*99-35-4*], TNB, benzite $C_6H_3O_6N_3$, M_r = 213.11 (I, R = H), attractive as high explosive, cannot be obtained by direct nitration of benzene, but only by indirect syntheses giving an expensive product used only for preparations of fine chemicals.

2,4,6-Trinitrophenol [*88-89-1*] $C_6H_3O_7N_3$, M_r = 229.11 (I, R = OH) TNP, picric acid, melinite, was extensively used in France during World War I because of lack of toluene, but was later replaced by trinitrotoluene (tolite), cheaper and non acidic. In some ammunitions, the ammonium picrate is still used.

N-Methyl N2,4,6-tetranitroaniline [*479-45-8*] Tetryl $C_7H_5O_8N_5$, M_r = 287 (I, R=N(CH_3)NO_2) has been used since 1905, noticeally for the production of boosters, after lubrication by graphite or calcium stearate. But it is now practically abandoned because some allergic incidents of dermatosis, and replaced mostly by RDX – wax mixtures.

Three nitroaromatic products with a picryl group remain for use as high explosives: TNT, HNS, and TATB.

2,4,6-Trinitrotoluene [*118-96-7*], TNT, tolite, $C_7H_5O_6N_3$, M_r 227.13 (**1**, R = CH_3), is produced by successive nitration of toluene, producing mono-, di-, and finally trinitrotoluenes. The mononitration products are 60 % *ortho*, 35 % *para*, and 3 – 5 % *meta* derivative.

1

The *o*- and *p*-nitro compounds give 2,4- and 2,6-dinitrotoluenes and then 2,4,6-trinitrotoluene (*meta*-directing effect of NO_2). However, *m*-nitrotoluene does not give the 2,4,6-trinitro derivative; other products are formed that reduce the stability or lower the melting point of the TNT. These impurities can be removed by the so-called selliting process or by fractional distillation of the mononitration products. The *m*- and *p*-nitrotoluenes are used as chemical intermediates, and the *o*-nitrotoluene is further nitrated to TNT. This method gives a product that is more easily purified.

For reasons of safety, quality, and cost, modern high-capacity plants use a continuous process. The solubility of organic products in mixed acids can be quite low, 0.5 – 15 wt %, depending on temperature and sulfuric acid concentration. Nitration is believed to occur in the acid phase. Consequently, the rate of interphase transfer and the intensity of stirring are important.

The plant employs a series of 8 – 16 mixer – settlers. The organic phase is transferred from the preceding settler together with the acid phase from a following or preceding settler (countercurrent or parallel nitrators) into a mixer maintained at a constant temperature (50 °C for mono-, 80 °C for di-, and 100 °C for trinitration). Acids may be added to adjust the composition. From the last settler, molten TNT overflows into other mixer – settlers that are used for washing and selliting.

The spent sulfuric acid can be concentrated to ca. 96 % but not to oleum. Using oleum in the process leads to a higher yield, a shorter starting time, and a more rapid reaction; consequently, fewer mixer – settlers are required for a given output, but a use or customer must be found for the spent acid.

Selliting is a process of washing with aqueous Na_2SO_3. A preferential reaction with the unsymmetrical TNT isomers gives deep-red water-soluble products. Selliting is applied to crude molten TNT above 80 °C, but with some losses. A continuous process may also be employed at 50 °C, with TNT suspension produced by cooling an aqueous emulsion with vigorous stirring [54]. The resulting spherules contain pure 2,4,6-TNT at their center, and a mixture of isomers in the outer layer. The use of $MgSO_3$, rather than Na_2SO_3, has been proposed [55]. The most economical treatment of the red spent water from

selliting is concentration followed by combustion.

Trinitrotoluene is used alone or mixed with PETN, RDX, or ammonium nitrate. It is also used in some industrial explosives.

Hexanitrostilbene [*20062-22-0*], HNS, $C_{14}H_6O_{12}N_6$, M_r 450.24, is formed by oxidation of TNT in methanol – tetrahydrofuran solution with aqueous NaOCl [58]:

Yields of 40 – 50 % are obtained in a continuous tubular reactor [59], [60]. Hexanitrostilbene can be crystallized from HNO_3 or acetone.

Hexanitrostilbene has the following unusual properties: the presence of 1 % HNS in molten TNT prevents the formation of cracks and crazes during solidification. With its low critical diameter (0.4 mm) it can be used as the core in silver or other metallic explosive cords. It remains stable and explosive over a very wide temperature range (−200 to 250 °C) and is thus usable in space [61].

1,3,5-Triamino-2,4,6-trinitrobenzene [*3058-38-6*], TATB, $C_6H_6O_6N_6$, M_r 258.15, is obtained by the following sequence:

The proximity of nitro groups favors the displacement of chlorine by ammonia. The reaction is conducted under pressure at 150 °C in toluene containing a little water. The product is washed with water to remove NH_4Cl. It has low solubility and is difficult to recrystallize [62], [63]. Although discovered in 1887, it first attracted attention after World War II. Since the 1950s interest has increased because of its thermal stability and outstanding insensitivity. Mixed with HMX and a fluorinated binder, it is used as a booster. It is, however, expensive (ca. 65 $/kg in the mid-1980s in the USA) because of the high cost and low availability of trichlorobenzene. Therefore, alternative synthetic routes have been developed. An extensive review of TATB is given in [9].

5.2.3. *N*-Nitro Derivatives

N-Nitro derivatives include primary nitramines $RNHNO_2$, secondary nitramines $RR'NNO_2$, nitramides, nitroureas, nitrourethanes, and nitroguanidines. There are no general synthetic methods. Sometimes it is possible to nitrate the precursor with HNO_3 alone as with tetryl. Often an *N*-acetyl, *N*-*tert*-butyl, or *N*-nitroso derivative is used as starting material. In some cases, nitric oleum is effective. The nitration of hexamethylenetetramine (hexamine) to RDX and HMX is more complicated.

1,3,5-Trinitro-1,3,5-hexahydrotriazine [*121-82-4*], $C_3H_6O_6N_6$, M_r 222.12, cyclotrimethylenetrinitramine, Hexogen, RDX.

Both RDX and HMX are stable in nitric acid over a wide temperature and concentration range, but are destroyed by aqueous sulfuric acid and are attacked by alkaline substances. Sulfuric acid should not be present during the synthesis.

1,3,5-Trinitro-1,3,5-hexahydrotriazine is manufactured by nitrolysis of hexamine with nitric acid alone or with acetic anhydride. These processes were developed before and during World War II.

The main process, called the Woolwich process, which does not use acetic anhydride, was developed in the United Kingdom and is used there and in France. The raw materials are hexamine and 98 – 99 % HNO_3 free of sulfuric acid. The reaction is complex and not completely understood.

Hexamine dinitrate is probably formed first, followed by intermediates that are oxidized or decomposed, exothermically and often violently, to produce RDX, which precipitates. Large amounts of nitrous gases and CO_2 are evolved along with water. The process must be continuous with careful control of temperature and flow conditions. The plant consists of three groups of stainless steel cascade-type reactors

with efficient stirring and cooling devices (jacket or coil). Nitric acid and hexamine are fed into the first group at a temperature of 20 – 50 °C. The homogeneous mixture overflows from the last reactor into the first one of the second group (the decomposers); this reactor is equipped with a large pipe for the escape of gases and a water feeder. The temperature is maintained between 75 and 82 °C, and water is continuously added to maintain a HNO_3 concentration of 55 wt %. The gases evolved are condensed in towers, producing 50 – 55 wt % HNO_3, which is reconcentrated. This first decomposer is the key to the operation. Foam must be avoided as well as thick crusts on which the stirrer could scrape, causing an explosion. In the third group of reactors, the suspended product is cooled and then continuously filtered and washed. The resulting RDX contains HMX (1 % max.) and some nitric acid, which can be removed by heating with water at 135 °C for 3 h in an autoclave. The yield based on hexamine is 78 – 80 %.

The RDX can be recrystallized or used directly, after desensitizing by wax or 10 % TNT to permit drying and transportation. Recrystallization from cyclohexanone or methyl ethyl ketone removes traces of acidity (required, for example, for use with aluminum powder) and produces crystals of the desired size.

A process without acetic anhydride was also developed in Germany in 1940 (KH process). A modification is the addition of NH_4NO_3 to react with all CH_2 groups of hexamine (K process).

The KA process was developed during World War II in Germany, and the Bachman process was developed and is used in the United States. Both processes use acetic anhydride, and the reactions are very complex.

To a solution of hexamine (1 part) in glacial acetic acid (1.65 parts) are added a solution of NH_4NO_3 (1.5 parts) in concentrated HNO_3 (2 parts) and acetic anhydride (5.2 parts) at ca. 65 – 72 °C. The mixture is maintained at that temperature for at least 1 h, diluted with water, and heated to hydrolyze impurities. The yield is ca. 80 – 85 %; nitrous fumes are not evolved.

The product contains ca. 8 – 15 % HMX, depending on the reaction conditions. An adequate source of acetic anhydride must be nearby, where acetic wastes can be dealt with. This process is easier to carry out than the process employing nitric acid alone, but its environmental problems are more difficult to solve. The same plant can be adapted to HMX production.

Both RDX and TNT are the basic components of almost all modern high explosives. They are mixed together, alone or with wax, or formulated with plastic binders. For a powerful and heat-stable explosive, RDX is preferred.

1,3,5,7-Tetranitro-1,3,5,7-tetraazacyclooctane [*2691-41-0*], $C_4H_8O_8N_8$, M_r 296.16 (**2**, R = NO_2), octahydrotetranitrotetrazocine, cyclotetramethylenetetranitramine, octogen, HMX, was discovered shortly before World War II as a byproduct of RDX synthesis by a Bachman-type process. It exists in four crystalline forms [4], [66], [67]. The β-form has the highest density (ϱ = 1.907 g/cm^3) and a shock sensitivity similar to that of RDX. Large crystals of the α-form are shock sensitive, but microcrystals are not.

2 **3**

HMX is now obtained directly by a modified Bachman process. In this batch process, acetic anhydride and a mixture of NH_4NO_3 and HNO_3 are added simultaneously at 44 ± 1 °C to hexamine dissolved in glacial acetic acid. After 15 min, the operation is repeated. The reaction mixture is aged at 45 – 60 °C, diluted with hot water, and refluxed for up to several hours. The suspended HMX is filtered off and washed until neutral. The HMX is obtained as small crystals of the α-form, which are transformed into the β-form by recrystallization from acetone or DMSO.

HMX can also be obtained via dinitropentamethylenetetramine (DPT, **3**, R = NO_2) [68]. In another process starting from hexamine, the diacetyl intermediates DAPT (**3**, R = $COCH_3$) [69] and DADN (**2**, R = $COCH_3$) are isolated, and this is followed by nitration with nitric oleum. However, since demand for HMX is now very low, production by this route has ceased.

The price of HMX is usually 3 – 5 times that of RDX. It is used when high performance is required (e.g., shaped charges). Both RDX and HMX are also used in propellants.

Other High Explosives. Numerous nitramine derivatives have been studied. For example:

Dinitroglycoluril [*55510-04-8*] (DINGU or DNGU ; **4**, R = H) has a high density (1.99 g/cm^3, X-ray) [100] and explosive properties close to those of TATB [70], [71], but at a much lower price. It can replace part of the RDX in mixtures with TNT and can be introduced as a component in gunpowder. Some comparative thermodynamic properties are studied [72].

4

It is prepared by continuous nitration of glycoluril with 98 wt % HNO_3 at 30 – 60 °C in cascade-type reactors.

Tetranitroglycoluril (sorguyl ; **4**, R = NO_2) prepared by nitration of DINGU with a mixture $HNO_3 - N_2O_5$, has a high density (2.01 g/cm^3), and detonation velocity (9300 m/s). Only one crystalline form is known. It must be coated or plastic bonded because it is sensitive to hydrolysis [70], [74], [72].

Hexanitrazaisowurtzitane (HNIW, CL-20). One way to obtain explosives of high crystal density is the synthesis of cage compounds such as HNIW, which was discovered in 1986 by A. Nielsen[98].

It is prepared by the reaction of benzylamine with glyoxal, followed by debenzylation and nitration. It exists in six crystalline forms [92], [93]; the ε-form has a density of 2.04 g/cm^3. Production has begun in pilot plants [91]. It can be used as a high explosives and in propellant formulations.

Oxynitrotriazole [*932-64-9*], ONTA, NTO, 3-nitro-1,2,4-triazol-5-one, was first reported in 1905, but its use as a low-vulnerability explosive was only discovered in 1979 [96],[73]. It has a high density (1.91 g/cm^3), good detonation velocity, low sensitivity to impact and friction, and good thermal stability (> 200 °C) [97].

It is manufactured in two steps: reaction of the semicarbazide hydrochloride with formic acid to give the triazolone, which is nitrated with nitric acid. The NTO is recrystallized from water. NTO is used in LOVA formulations, some of which were tested in a joint LOVA programme of the USA, UK, Germany, and France.

Ammonium dinitramide (ADN), $NH_4^+N(NO_2)_2^-$, ϱ 1.83 g/cm^3, *mp* 92 °C, is a carbon-free ammonium salt that was discovered and developed in the former Soviet Union in the 1960s and has in the mid 1990s been disclosed [99]. ADN is almost as hygroscopic as ammonium nitrate and very insentive. It is of interest as a component of certain explosive mixtures and as a clean propellant.

6. High Explosive Mixtures

Explosives are used for global or directed destruction (bombs, torpedoes, mines, reactive armors, and warheads) or for pyrotechnics. Among pure compounds, only TNT and trinitrophenol are sufficiently insensitive to be loaded in large quantities by casting. Small quantities of other pure compounds are sometimes used for detonators or cutting or transmitting cords.

For flexible wrapped cords, the pure explosive (e.g., PETN) flows continuously through a funnel to form a flowing stream that is wrapped in a thin plastic band. Thread is immediately woven on the plastic-enclosed explosive, and this is again encased with plastic by drawing through a die, which also helps adjust the loading density.

For metallic cords, the high explosive (PETN, RDX, HMX, or HNS) is introduced into a metallic tube (lead, copper, or silver), which is drawn through dies until the desired size and cross section are obtained.

Loading Processes. In casting processes, the explosive is employed as a solution or a liquid suspension; it is cast into the shell or in the mold, where it crystallizes on cooling (physical process) or solidifies by the cross-linking of a polymer (chemical process). In pressing processes, the explosive is introduced in granular form into a mold or shell and pressed with a piston at a pressure of 10 – 300 MPa; conditions depend on the munitions size, the binder, and the required mechanical properties. Special shapes are prepared by laminating or calendering.

Flexibility is increased by the use of blends, which can enhance explosive performances while preserving safety and reducing cost. Special effects, such as delayed detonation, are possible with improved safety and high-temperature stability.

6.1. Desensitized Explosives

Because of their sensitivity and high melting points, RDX, PETN, and HMX must be desensitized before casting or pressing. This is achieved by coating the particles with wax, sometimes with addition of graphite as a lubricating and antistatic agent. The beeswax used in the past has been replaced by paraffin or synthetic waxes, which give more reproducible results. The wax content in the explosive mixture is usually 2 – 10 wt %.

In the simplest process, the particles are coated in hot water. The explosive (RDX, for example) is vigorously stirred in water and heated slightly above the melting point of the wax, which is introduced and dispersed on the particles. The mixture is cooled by the rapid introduction of cold water, without formation of crusts on the vessel walls. The suspension is filtered and dried. Coating agents melting above 100 °C are applied in a solvent (e.g., butyl acetate), which is removed by steam distillation. If the explosive is sensitive to hot water, the solvent is removed by filtration, possibly preceded by evaporation under vacuum. These processes are also used to prepare ternary mixtures of explosive aluminum and wax.

Detonation velocities can be obtained close to those of the pure explosives; e.g., for a mixture of 94.5 % RDX, 5 % wax, and 0.5 % graphite, $D = 8600$ m/s at $\varrho = 1.76$ g/cm^3 ($D = 8850$ m/s at $\varrho = 1.82$ g/cm^3 for pure RDX). However, large loadings are difficult to carry out because of problems with homogeneity, brittleness, porosity, and cost. The process is very useful for automatic filling of press-loaded small munitions.

6.2. TNT Mixtures

Molten TNT (*mp* 80 °C) is compatible with many explosives and other products, providing a castable melt above 80 °C. Among the products most frequently added are ammonium nitrate, to obtain very cheap munition loadings (amatols), and nitramines (RDX or HMX) or other high explosives (PETN, NTO), to improve performance. Mixtures containing 50 – 75 wt % RDX are used in bombs and warheads such as shaped charges. Some castable blends contain aluminum powder (tritonals, ammonals, Torpex, and HBX 1 and 3).

Wet and dry processes are employed. The former, the same as that used for desensitizing with low-melting wax, has cost and safety advantages. Almost the entire process is carried out under water. In France, RDX coated with 10 wt % TNT is produced in this manner, because its transportation as a dry product is allowed. However, air bubbles on the RDX crystals can create difficulties in loading.

In the dry process, the components are added dry to molten TNT with stirring, and the mixture is cast in shells. Wet RDX can be added to TNT at ca. 95 – 100 °C; the water is removed by decantation and evaporation.

Blends of TNT are used in the large-scale production of munitions. Shaped charges can be obtained by controlled sedimentation of the molten mixture. Crack formation in TNT during cooling can be controlled by the addition of 1 % HNS.

Explosive performance is restricted by the condition that the mixture must be pourable; for example, for a blend of RDX: TNT of 70: 30 (wt %), $D = 8060$ m/s at $\varrho = 1.73$. (Since $\varrho_{\mathrm{theor}} = 1.765$, the porosity is ca. 2 %.)

For blends with higher RDX or HMX content, a special apparatus such as a porous piston is used. Because of the danger of detonation by fire, mixtures of RDX with TNT are now forbidden on ships by some countries.

6.3. Plastic-Bonded Explosives (PBX)

Two different procedures are followed which improve the performance of new munitions.

Desensitized Explosives. Some new warheads require improved mechanical properties and stability at high temperature. Waxes are replaced by thermoplastics or by other plasticized polymers (nitrocellulose).

The manufacture of these plastic-bonded explosives resembles the use of waxes dissolved in a solvent immiscible with water. The molding powder is pressed, often in a heated and evacuated mold; for large charges, machining is necessary to obtain homogeneous charges of complex shapes with good mechanical properties at high temperature.

Examples include RDX or HMX boosters bonded with polyamide and mixtures of HMX and TATB containing 10 wt % fluorinated polymer [95]. Use is limited by the high cost of the pressing machines and the length of the processing cycle, especially for large charges.

Castable Explosives [75], [76]. For larger charges, mixtures are used of an explosive with a liquid binder, which is then cross-linked (composite explosives). A similar process is used for composite propellants. Composite explosives are being developed for uses requiring high accuracy and low vulnerability (LOVA explosives).

The liquid binder is introduced first into a mixer equipped with S-blades. A mixture of a diisocyanate and a diol (hydroxy-terminated polyether or polybutadiene) is usually employed in a precise ratio, with a precise quantity of a cross-linking agent such as a triol. The dry solid explosive (RDX, HMX, or PETN) is then added and mixed under vacuum with additives (e.g., surfactants) and a catalyst providing a pot life, i.e., the mixture remains pourable, of a few hours. During this time the mixture is cast, sometimes under pressure or by injection, in vibrating and evacuated molds or shells. The molds are cured in an oven for a few days. Two different compositions may be cast, one over the other (bicompositions), to produce special detonation waves.

The main advantage of these formulations is their low sensitivity, especially against bullets, impact, and friction, and the difficulty of the transition from combustion to detonation. The mechanical properties can be excellent, and thermal stability is fair.

Among the drawbacks are the slow curing and high cost when a multimodal particle-size distribution is used to increase the explosive content. The detonation velocity is diminished by the inert character of the binder; it can be estimated by the Urizar formula [7, pp. 8 – 10], [77]. Energetic binders improve the detonation velocity, but increase sensitivity. A review of energetic binders is given in [15], [79]. The use of thermoplastic elastomers as binders is of interest for environmental reasons since they facilitate the dismantling of ammunition.

7. Industrial Explosives

For more than 350 years explosives have been employed to mine ores and minerals. The annual consumption of explosives by each of the largest Western European consuming countries is around 40 000 t. World annual consumption of industrial explosives is at least 5×10^6 t, 75 % of which is ammonium nitrate – fuel oil (ANFO).

During the first 250 years of this period, only black powders were known and used, but fundamental changes occurred in the 1860s (invention of dynamite and blasting cap by Alfred Nobel), 1950s (ANFO), and 1980s (emulsions). The search continues for less expensive products and safer techniques for production and field use in mines, quarries, and road, tunnel, and dam construction. At the same time, the introduction of new products is restrained by the cost of existing investments and by safety and environmental regulations.

7.1. Dynamites

Gelatine dynamites are powerful explosives whose main ingredient is nitroglycerin. They

were invented opportunely to replace black powder in the construction of railroad and tunnels and gave great impetus to the use of explosives. Although diminished in importance since the 1950s and progressively replaced by new types of explosive, dynamites are still widely used because of their excellent qualities.

A detonation velocity range from 4300 to 7500 m/s provides high brisance. Sensitivity to initiation by cap or detonating cord is very good, as is the flashover coefficient. Density (ca. 1.5 g/cm^3), water resistance, and detonation pressure are high.

The composition of dynamites has changed only slightly since their origin. Nitroglycerin, gelatinized by nitrocellulose, has been totally or partially replaced by nitroglycol to reduce cost and permit lower operating temperatures. However, nitroglycol is more toxic than nitroglycerin, and its use is limited in some countries. Oxidizers such as ammonium nitrate reduce the cost of low-energy formulas. Combustible components (wood meal, peat, silicon, and aluminum) and other additives (sodium nitrate, ammonium chloride, and sodium chloride), provide formulations with specialized properties.

The consistency of such mixtures varies according to the nitroglycerin – nitroglycol content. Gelatin dynamites containing 20 – 40 wt % of nitroglycerin – nitroglycol form a plastic paste that may be made into cartridges after cutting or extrusion. Dynamites containing 10 – 20 wt % nitroglycerin – nitroglycol are powdery, and tampers are required to make cartridges. They have been largely replaced by the new explosives, except for use in coal mines, where the potential presence of dangerous dust and gas means that only very safe explosives with the lowest possible detonation temperature should be used. Permissible explosives for these applications usually contain a large amount of ammonium nitrate and sodium chloride, the endothermic melting of which absorbs much of the energy released by the detonation. Degrees of safety in coal mines are defined by national regulations. In France the classes are *rocher*, *couche*, and *couche améliorée*. The first refers to less safe explosives, permitted for underground use only. Dynamites are marketed in cylindrical paper, cardboard, or plastic cartridges. The characteristics of the leading products of Nobel Explosifs France are given in Table 4.

7.2. Ammonium Nitrate Explosives

Ammonium nitrate (AN) explosives were developed in European countries to replace explosives made with chlorates. They appeared later in the United States (Nitramon, DuPont, in 1935).

The French AN explosives, are made with ammonium nitrate (ca. 80 wt %) sensitized with a nitro compound (TNT, PETN, or their mixture, called pentolite). Formulas include aluminum powder and additives. These products are characterized by their good production safety and low production cost. They show good sensitivity when set off by caps or detonating cords. However, they are sensitive to humidity. Properties of the representative product Securex 80 are as follows:

Composition, wt %	
Ammonium nitrate	81.5
High explosive	16
Aluminum	0
Mass energy, kJ/g	3.51
Detonation velocity, m/s	4800
Flashover coefficient, cm	2
Detonating pressure	6.34
Density, g/cm^3	1.10

Ammonium nitrate explosives made in the United States contain dinitrotoluene but no nitro high explosive. They are produced by blending and as a result are not cap sensitive. The U.S. Government, followed by other governments, has established a category with relaxed rules for the transport and storage of these explosives. This category was first called NCN (nitrocarbonitrate) and is now known as blasting agents. They have been progressively replaced by water gels and emulsions.

7.3. Ammonium Nitrate – Fuel Oil Explosives

Ammonium nitrate – fuel oil (ANFO) explosives have been developed since 1955. They are made of porous prills of ammonium nitrate (ca. 94 wt %) soaked in mineral oil, usually domestic fuel oil (ca. 6 wt %). In some cases, aluminum powder is added to increase explosive strength.

Ammonium nitrate – fuel oil explosives are ordinarily used in bulk, although some countries

Classification	gelatin	gelatin	powder
Application	general and underground	general and underground	permissible
Mass energy, kJ/g	3.97	4.15	1.78
Detonation velocity, m/s	6000	6500	2200
Flashover coefficient ∗, cm	8	10	10
Cartridging density, g/cm^3	1.45	1.45	1.10
Detonation pressure ∗∗	13.05	15.32	13.31

∗ Maximum distance at which a cartridge of diameter 30 mm and weight 50 g has a 50 % probability of iniating another cartridge.
∗∗ Calculated with the formula $\frac{1}{4}\,AD^2$.

limit their use to cartridges. They can be made on-site in a mobile unit, often mounted on a truck (ANFO truck). They are inexpensive and safe to handle, but low in strength, detonation velocity, and detonating pressure. In addition, they cannot be used in the presence of water. Because of their very low sensitivity, they require powerful primer charges, powerful detonating cords, dynamite relay cartridges, and boosters. The densities are low. Properties are listed in Table 5.

Table 5. Properties of ANFO explosives for general applications

Property	N 135	D7 fuel
Composition, wt %		
Ammonium nitrate	91	94.3
Fuel oil	4	5.7
Aluminum	5	0.0
Mass energy, kJ/g	3.43	2.74
Detonation velocity, m/s	3900	3700
Detonating pressure	3.42	2.84
Density, g/cm^3	0.9	0.83

7.4. Slurries and Water Gels

A new class of industrial explosives, known as water-explosives has been developed since 1956; they contain no nitroglycerin and are based on a solution of nitrates, thus containing considerable water (10 – 15 wt %). During the 1970s and 1980s, water explosives have took over much of the market, at the expense of dynamites and AN powders, because of their lower production cost and greater safety during production and handling.

Water explosives are used in cartridges or in bulk form. The bulk explosives are poured or pumped into the blast holes. Cartridges are formed with a continuous through-circulation device (CHUBPACK) in cylindrical plastic envelopes closed by metal clips.

Slurries and water gels are made of aqueous solutions of ammonium nitrate and sodium or calcium nitrate gelled by the addition of guar gum or cross-linking agents. They are sensitized by nitro explosives, organic amine nitrates, or by paint-grade aluminum. Combustible materials, such as aluminum, urea, sugar, or glycol, are mixed with these solutions either continuously or discontinuously.

The presence of reactive aluminum, water, and ammonium nitrate requires careful control to avoid chemical side reactions. The properties of water gel explosives and slurries marketed in France are listed in Table 6.

Table 6. Properties of water gel and slurry explosives for general applications

Property	Hydrolite AP, in bulk	Gelsurite 3000, in cartridges
Composition, wt %		
Nitrates	46	61.6
Water	15	13
Aluminum	0	15
High explosive	27	0
Mass energy, kJ/g	2.70	3.87
Detonation velocity, m/s	5100	4000
Flashover coefficient, cm	0	5
Detonating pressure	9.75	4.80
Density, g/cm^3	1.50	1.20

7.5. Explosive Emulsions

Since the cost of sensitizer for water gels is high, other formulas based on nitrate solutions but containing cheaper raw materials have been investigated. This led in 1962 to “water-in-oil” and “oil-in-water” emulsions, whose sensitivity

is due to the presence of air bubbles; these are most efficiently introduced by means of hollow glass bubbles or chemical gassing techniques.

Emulsions are produced, like water gels, by a continuous or a batch process and can be used in cartridges or in bulk form. Although the emulsions are neither gelled nor reticulated, their storage life has been considerably improved by using sophicated emulsifiers.

Emulsions differ from nitrate-fuel oil, nitrate, and water gels in their higher detonation velocity. The properties of typical emulsion-type products of Nobel Explosifs, France are listed in Table 7. The emulsions are sensitized by a chemical gassing process, apart from Iremite 2500s, the formulation of which includes microspherical glass bubbles.

7.6. Uses

The energy provided by explosives is used in a number of ways, including explosive cladding (see Section 3.3), metal working (forming, welding, and cutting), and shearing by pyrotechnics systems. However, the principal nonmilitary use of explosives is in mining. This application is governed by extensive safety regulations and is subject to competition from increasingly powerful mechanical means of extraction, such as mining machines, rippers, and tunnel-boring machines. Although the use of explosives entails such drawbacks as noise, vibration, and smoke, the technique is flexible, easy to use, and low in capital and material cost.

When using bulk explosives, cost is reduced because loading in cartridges is unnecessary. In addition, they fill the entire blast hole, allowing the possibility of enlarging the drilling pipe. These explosives make up half of those used in Europe, and over three-fourths of those used in the United States. They can be produced on-site in mobile units (ANFO truck, mix pump truck), which, however, are usually not economical for small-scale European operations. It is also possible to sensitize the bulk explosives just before filling in the blast holes. In this case, the unsensitized product is not entirely subject to the regulations for producing, handling, transporting, and storing dangerous materials.

The safety of explosives has been significantly improved by the use of nonelectric detonating devices with low-charge detonating cords or electronic detonators. The use of computers and sequential blasting machines has optimized firing systems, led to efficient use of explosive, and reduced environmental impacts such as noise and vibration.

8. Test Methods

Tests of secondary explosives are designed to study detonation phenomena, to approve a product, and to verify that manufactured lots meet the requirements (i.e., quality control).

Detonation phenomena (10^{-9} to 10^{-12} s) are observed by laser interferometry, streak cameras, and X-ray flashes, all electromagnetic methods. The very high instantaneous pressures (10 – 40 MPa) are measured, e.g., with low-impedance piezoresistive manganin gauges (Cu–Mn–Ni alloy) [78] or with fluorinated piezo polymers as shock sensors [101]. Phenomena are modelled based on Becker – Kistiakowsky – Wilson (BKW) [32] or Jones – Wilkins – Lee (JWL) [33] equations developed in the United States at the Los Alamos Scientific Laboratories (LASL) and the Lawrence Livermore National Laboratory (LLNL).

Tests to approve a product measure detonation velocity and pressure, energy released, ability to initiate or transmit detonation, and critical diameter. They also determine the safety characteristics in use, storage, and transportation.

The verification of a lot is usually based on the determination of physical properties (melting point, particle size, specific area) and chemical analysis. Safety and storage characteristics must match those of the approved product.

Codified tests for military use are published in the United States as military specifications (MIL), in France as *Manuel des modes opératoires,* in the Federal Republic of Germany as VTL, in the United Kingdom as DEF. STAN, and at NATO as STANAG. Japan issues *Japanese Industrial Standards* [80]. Unified and standardized European explosives tests (EXTEST) are published in *Explosifs* (Belgium, 1960 – 1970), in *Explosivstoffe* (FRG, 1971 – 1973), in *Propellants and Explosives* (FRG, 1977 to 1981), and in *Propellants, Explosives, Pyrotechnics* (1982 to date) (see also [7], [10]).

Table 7. Properties of explosive emulsions used for general and underground applications

Property	Iremite 1000 in cartridges	Iremite 4000 in cartridges	Iremite 2500s in cartridges	Gemulsite 100 for pumping
Mass energy, kJ/g	3.34	3.92	3.51	3.49
Detonation velocity m/s	5300	5300	5500	5100
Flashover coefficient, cm	>5	>5	5	
Detonating pressure	8.43	8.43	9.08	7.80
Density, g/cm^3	1.20	1.20	1.20	1.20

8.1. Performance Tests

Detonation Velocity. The *Dautriche method* is based on a comparison of the velocity in two parts of a circuit, composed in one section of a known detonating cord and in the other of a cartridge made with the test sample. The detonation wave fronts run in opposite directions in the two segments and collide at a precise point [81].

More sophisticated electrical or optical methods are also available. For example, electrical wires (switches), inserted into a cylindrical cartridge at precise locations, are short-circuited by the passage of the detonation wave, giving a signal that is recorded on a chronograph. Other methods use streak cameras. The detonation wave is built up at a distance from the initiation point, and this occurs only if the cartridge diameter is large enough. Therefore, this test requires an adequate quantity of explosive.

Energy Output [5], [81]. In the *lead block test*, strength or CUP (*coefficient d'utilisation pratique*) is measured by the expansion of a cavity in a lead block caused by the detonation of a sample of explosive, in comparison with a standard (PETN, picric acid, or TNT).

In the *ballistic mortar test,* the energy released by detonation gases is measured in a steel mortar consisting of two cavities: the first contains the explosive, and is connected to the second, which contains a projectile. The assembly is suspended by a pendulum, and when the projectile is driven out by the detonation, the recoil moves the mortar to an angle that is compared to that given by a standard explosive.

The *Kast method* is used to evaluate explosive brisance, a value related to the product ϱD^2 where $\varrho =$ density and $D =$ detonation velocity. The crushing of a copper cylinder by the detonation is compared to that obtained with a standard explosive.

The *cylinder test* has been studied at the Lawrence National Laboratory, Livermore, California, [82]. The velocity transmitted by a cylindrical rod of explosive to a tightly fitting copper tube is measured by a streak camera.

For more routine measurements, the *Défourneaux test* can be used (push-plate test). A metal plate lies on an explosive plate, which is detonated by a linear wave generator. During the detonation, the metal plate is continuously bent to an angle, which is observed, for example, by X-ray flash [83]. Among other tests is underwater explosion, with measurements of the bubble produced.

Other Performance Tests. In one of the critical diameter tests, the detonation propagation of metal cords (copper or silver) filled with an explosive of known density is observed as a function of the inner diameter. In another method, a conical charge is used.

Other tests include the determination of the coefficient of transmission of detonation, the sensitivity to initiation, the self-excitation coefficient (maximum distance between two cartridges loaded with the same explosive, allowing the initiation of one by the other), and the plate-dent test.

8.2. Safety

Stability. Aging effects are frequently determined by the *vacuum stability test*, in addition to the usual chemical methods. It can be used to study the compatibility between explosives and other materials.

The sample is placed in a test tube fitted with a manometric capillary glass tube; the other end of the tube dips into a cup of mercury. The tube is evacuated and the sample is heated, usually

between 80 and 130 °C. The variation of the inner pressure in the tube is shown by the mercury level. Pressure usually increases during the first few hours with the release of traces of moisture and volatile substances. Afterward, during a period of 100 h, the rise in pressure can be linear (constant decomposition rate) or more rapid (autocatalytic decomposition).

Sensitivity. The *impact sensitivity* of an explosive is the minimum energy that causes quick decomposition [5], [13], [84]. The test conditions strongly influence the results, which (given in Joules) are only orders of magnitude. The classification of explosives depends on the apparatus and the test conditions.

In the Bruceton test for impact sensitivity, the stimulus after a positive result is lowered by one unit and raised after a negative result. The value of the sensitivity is obtained as the mean of 30 – 50 trials. Probabilistic values are also determined.

The procedures differ in the size and placement of the sample and the use of tools exposed or covered with sandpaper. The reaction may be followed visually, aurally, audiometrically, or by examination of gas evolution.

Tests are prescribed by the U.S. Bureau of Mines, Picatinny Arsenal (United States), Explosives Research Laboratory (United States), BAM (Federal Republic of Germany), Julius Peters (Federal Republic of Germany, France), Rotter (United Kingdom, Canada), and Aubertein (France). Another test is the Susan projectile-impact test, where a projectile containing ca. 450 g of explosive is directed against a hard target at selected velocities.

The *friction sensitivity test* is even more difficult to reproduce than the impact sensitivity test. A thin layer of sieved explosive on a fixed surface is rubbed by a hard or abrasive surface moved by translation (Julius Peters apparatus) or by rotation (U.S. Bureau of Mines) under adjustable pressure.

Impact and friction are combined in the skid test (Pantex) and the Popolato test; an explosive sphere is projected against a sand-coated target plate at defined impact angles.

In the *electrostatic sensitivity test*, a small quantity of explosive is placed between two electrodes. A capacitor discharge causes a spark to pass between the electrodes through the explosive. The sensitivity is expressed by the minimum energy required to decompose the sample.

In addition to differential thermal analysis (DTA) and thermogravimetric analysis (TGA), the following *heat sensitivity tests* are employed:

1) The sample is subjected to a constant increase of temperature and the decomposition or ignition temperature is noted; the result depends on the quantity of explosive and the rate of heating.
2) The sample placed in a small bulb is dipped into a Wood's metal bath maintained at a fixed temperature. The time to decomposition is noted, or the temperature at which a decomposition occurs after 5 s.
3) The sample is ignited in a gutter and the burning rate measured.
4) The sample is externally heated in a closed or half-closed vessel. The tendency to burn or to detonate is observed (steel-sleeve test).
5) The sample is heated at a given rate in a closed vessel. The time of detonation or the temperature at which the sample detonates after a given time is noted (cook-off test).

To test the *sensitivity to initation* through a spacer (card-gap test), a sample in a steel tube is subjected to the detonation of a standard booster explosive separated from the sample by a barrier of cellulose acetate cards of 0.19 mm thickness [8]. The minimum number (N^-) of cards that prevent transmission of detonation fixes the legal class of the explosive for transportation and other regulations.

To obtain a LOVA agreement (MURAT in France), the following tests must be carried out on ammunitions: bullet and fragment impact, slow and fast cook-off tests, reaction towards a shaped-charge jet, and sympathetic reactions. The results depend on storage of the ammunitions, their design, and on the properties of the propellants and explosives they contain [94], [19, 20]. These investigations are supported by the NATO Insensitive Munitions Information Center (NIMIC, Brussels).

9. Legal Aspects and Production

Governments regulate the possesion, production, storage, packaging, shipping, and trading

of explosives. Periodic inspections and labeling prevent theft. Tagging the explosive permits tracing its origin.

9.1. Safety Regulations

Originally, each country established its own regulations; the standardization recommended by the United Nations was published in 1984 [85]. Substances are classified according to the type of risk involved, unless they are too dangerous to ship. Explosives are in Class 1, which contains five subdivisions [85]:

1) Substances and articles that present a bulk explosion hazard
2) Substances and articles that present a projectile hazard but not a bulk explosion hazard
3) Substances and articles that present a fire hazard and a minor blast and/or projectile hazard without a bulk explosion hazard
4) Substances and articles that present no significant hazard
5) Insensitive substances that present bulk explosion hazard, but very little probability of initiation or transition from burning to detonation under normal transport conditions

Class 1 is restricted, containing only registered substances; for new substances, test results must be presented. Simultaneous transport and storage are permitted for "compatibility groups".

The transportation regulations specify packaging, labeling, an identifying insignia on vehicles, compatibilities, and maximum load and safety devices on vehicles.

Manufacture and storage are governed by the TNT equivalency, which is defined as the quantity of TNT producing the same effects as 100 kg of the explosive [86].

The expression $d = k\,Q^{1/3}$ gives the safe distance from a load Q of explosive (expressed as TNT equivalent), where the constant k depends on the presence of walls or other protection.

9.2. Production of Military Explosives

High explosives are manufactured by private companies in many countries, e.g., United Kingdom, Germany, Norway, Sweden, Switzerland, and Japan.

In the United States, research and development involving high explosives are often undertaken in military laboratories. Production is conducted by arsenals or by private companies under the GOCO system (Government owned – contractor operated), in which investments and factories are owned by the government. The product is government property and cannot be sold by the operating company.

In Spain production is shared between a national company and private ones. In France military secondary explosives are manufactured by a national company; munition loading is carried out by a national and private companies.

Production figures and prices are generally not available.

10. Toxicology and Occupational Health

Raw Materials. Both acids (HNO_3 and H_2SO_4) and benzene derivatives (toluene and chlorobenzene) are of concern [4]. The usual safety measures must be followed to protect eyes, skin, and respiratory tract. Red fumes of nitrogen oxides, formed normally or by accident, can induce lung edema two days after exposure; the use of a gas mask is recommended.

Explosives. Some *primary explosives* are toxic (mercury fulminate and certain lead salts), but the toxic hazards are far below those arising from high sensitivities to detonation. Among the secondary explosives, *nitroglycerin* and other liquid nitrates exhibit hypotensive action accompanied by headaches and, in chronic cases, by methemoglobinemia. A tolerance to nitroglycerin can be developed. These substances are usually absorbed through the skin rather than by inhalation. For nitroglycerin and glycol dinitrate, TLV = 1.5 mg/m^3. *PETN,* which like nitroglycerin is prescribed for heart diseases, has a very low vapor pressure and is not readily absorbed by the skin.

The toxic effects of *TNT* include blood changes, cyanosis, methemoglobinemia, and toxic hepatitis. It is introduced by inhalation, ingestion, and skin absorption; at inhalation level,

TLV = ca. 1 mg/m^3. Dust in the plant is to be avoided.

Tetryl can induce an allergic dermatitis,therefore its use is practically abandoned.

Both *RDX* and *HMX* have negligible vapor pressures. They do not penetrate the skin and their toxicity is very low. However, there have been reports of epileptiform convulsions, without liver involvement, or carcinogenic or mutagenic effects. Dust formation should be avoided and masks should be worn.

1. Introduction

Naturally occurring oils and fats are liquid or solid mixtures consisting primarily of glycerides. Depending on whether they are solid or liquid at ambient temperature, they are referred to as *fats* or *oils*, respectively. Naturally occurring oils and fats always contain minor constituents such as free fatty acids, phospholipids, sterols, hydrocarbons, pigments, waxes, and vitamins. The nomenclature rules for glycerides have been summarized [18].

History. A century ago ecological, religious, and social factors still played a more important role than technology in the choice and utilization of oils and fats.

Primeval humans utilized animal fats, making cheese and butter from goat's milk. Oilseed plants were cultivated during the neolithic period. Poppy seeds have been found in remains of Bronze-Age bread; rapeseed and linseed, together with millstones, have been found in Bronze-Age dwellings.

Linseed, almonds, and sesame seed were part of Egypt's natural flora. Sesame oil had mythical significance. The oil-bearing safflower plant is still grown in Egypt. Olive oil came from Palestine, Syria, and Crete. The Phoenicians and Greek colonists introduced the olive tree to Sicily and Italy. Cotton is one of the oldest cultivated plants; it was grown 2600 years ago in India as a source of both oil and fiber. Soy and hempseed are mentioned as oilseed plants in a Chinese document of 2838 B.C.

The oilseeds were ground with a pestle and mortar or between stones. Simple mills of the type still being used in some developing countries – a concave stone rotating on a convex one – also evolved. The Egyptians developed the sack or expeller press. The Greeks and Romans used a grinding device known as the "trapetum". In North Africa, mechanical presses were used in processing plants that approached the size of modern factories.

The processing of oil fruits and seeds in Central and Northern Europe advanced more slowly. Oilseeds, primarily linseed, hempseed, and rapeseed, were pulped in hollowed stones, and the oil was expelled from the pulp by pressing between two cloth-covered frames. This domestic-type process was practiced up to the 16th century. Industrial oil milling developed primarily in regions where linseed was grown extensively. A wood engraving dated 1568 depicts an oil mill with a horse-drawn vertical millstone on a stone bed. The ground oilseed was heated in a kettle over an open fire and finally "beaten" in wedge presses.

Animal fats were obtained by rendering fatty tissue and by churning cream. Up to the middle of the 19th century, tallow and butter were the most important edible fats in Europe, lard and vegetable oils playing only a minor role.

Toward the end of the 19th century the production of oil by hydraulic pressing and solvent extraction was introduced. This process gave relatively high oil yields but necessitated posttreatment of the oils by neutralization, bleaching, and deodorization.

The invention of margarine in the 1870s gave further impetus to the oil-processing industry. With the discovery of oil hydrogenation (hardening) at the beginning of the 20th century, liquid oils could be converted into spreadable, consistent fats. In the 1930s, interesterification and fractionation were developed as further methods to modify the consistency of oils and fats.

Apart from being used for edible purposes, oils and fats are referred to in the Old Testament as cosmetic products and lamp fuel. Anointing with oil symbolized royal dignity. HOMER and HERODOTUS refer to the use of fats as "process-

ing aids" during weaving. The ability of fats to calm waves was studied by Indian scholars 3000 years ago. The Egyptians supposedly used fats as lubricants to transport stone blocks. They were also familiar with the use of drying oils in varnishes and paints.

The elucidation of the chemical nature of fats was initiated by SCHEELE, who produced glycerol from olive oil around 1780. CHEVREUL subsequently (ca. 1815) recognized that fats were predominantly esters of fatty acids and glycerol.

Modern research and development is focussed on the application of new biotechnological principles to the production and modification of oils and fats [19], as well as on nutritional aspects, problems of trace contaminants, and environmental pollution. The breeding of new plant varieties is an important method for increasing the types of oils and fats. Examples are new varieties of rapeseed (low erucic acid content), safflower, and sunflower (high in oleic acid). New sources of oils and fats are being exploited by cultivation of wild plants such as the jojoba and *Cuphea* shrubs.

2. Composition

2.1. Glycerides

Naturally occurring fats contain about 97 % triglycerides (triacylglycerides), i.e., triesters of glycerol with fatty acids; up to 3 % diglycerides (diacylglycerides); and up to 1 % monoglycerides (monoacylglycerides). Tri-, di-, and monoglycerides consist of 1 mol of glycerol esterified with 3 mol, 2 mol, or 1 mol of fatty acid, respectively. The triglycerides of naturally occurring oils and fats contain at least two different fatty acid groups. The chemical, physical, and biological properties of oils and fats are determined by the type of the fatty acid groups and their distribution over the triglyceride molecules. The melting point generally increases with increasing proportion of long chain fatty acids or decreasing proportion of short chain or unsaturated fatty acids. Milk fat (butterfat) and coconut oil, which contain a high proportion of C_6–C_{12} fatty acids, have lower melting points than fats such as tallow and lard, which contain predominantly C_{16} and C_{18} fatty acids. Vegetable oils are liquid at ambient temperature because of their high proportion of unsaturated fatty acids.

The properties of a triglyceride are also determined by the position of the various fatty acid groups in the triglyceride molecule (i.e., 1-, 2-, or 3-position). The total number N of possible triglycerides (including positional isomers) from x different fatty acids is

$$N = \frac{x^2 + x^3}{2}$$

However, the proportions of different triglycerides in a naturally occurring fat generally do not conform to a statistical distribution. In vegetable oils and fats, unsaturated fatty acids are linked preferentially to the 2-position of the glycerol group, whereas in animal fats they appear primarily in the 1- and 3-positions ("2-random" and "1,3-random" distributions) [20]. Extreme examples of nonrandom distributions of fatty acid groups over the triglyceride molecule are cocoa butter (ca. 40 % 1-palmito-3-stearo-2-olein) and lard (ca. 20 % 2-palmito-1,3-diolein).

2.2. Fatty Acids

The fatty acids that form the triglycerides of naturally occurring oils and fats are predominantly even-numbered, straight-chain, aliphatic monocarboxylic acids with chain lengths ranging from C_4 to C_{24}. Unsaturated fatty acids differ in number and position of double bonds and in configuration (i.e., cis or trans isomers). The more common fatty acids are known by trivial names such as butyric, lauric, palmitic, oleic, stearic, linoleic, linolenic (→ Fatty Acids). Crude oils contain significant amounts of free fatty acids.

The chief fatty acids in some commercial oils and fats are listed Tables 1 (saturated fatty acids) and 2 (unsaturated fatty acids). The fatty acid composition of most vegetable oils and fats is relatively simple; they consist predominantly of palmitic, oleic, and linoleic acids [20]. The fatty acids of land-animal fats mainly have a chain length of C_{16} or C_{18}. They are formed by biosynthetic conversion of carbohydrates, proteins, or fats, or originate directly from ingested fat.

Ruminant fats contain 5 – 10 % trans fatty acids, which are produced from linoleic and

linolenic acid in the rumen. Marine oils contain a high proportion of polyunsaturated fatty acids with a chain length of $C_{20}-C_{24}$. Land-animal fats and marine oils contain numerous odd-numbered and branched fatty acids in trace concentrations. More than 80 different fatty acids have been found in milk fat, and more than 40 in lard. However, most of these fatty acids occur only in traces. They can be of industrial significance for some oils and fats and they can play a role in the identification of fats and their detection in mixtures.

The fatty acid composition of a naturally occurring fat is determined genetically. The fatty acid composition of oleaginous seeds can be changed by developing new varieties. Examples are low-linoleic safflower and sunflower oils and low-erucic rapeseed oil. Environmental factors can influence the fatty acid composition within certain limits. The proportion of unsat-

[c] $x > 1$.

urated fatty acids in the glycerides of linseed, soybean, and sunflower oils, for example, generally increases as the climate becomes colder and wetter. The subcutaneous fats of marine animals living in the colder parts of the oceans have a particularly high content of unsaturated fatty acids and thus a relatively low melting point. Linoleic acid cannot be synthesized by the animal or human organism and is hence referred to as an "essential" fatty acid.

Naturally occurring oils and fats are distributed homogeneously in varying concentra-

tions in vegetable and animal tissues. In plants they are found predominantly in the seeds and the fruit pulp where they serve as a source of energy.

Biosynthesis. The synthesis of fatty acids in plants and animals generally starts with "activated" acetic acid, i.e., acetyl coenzyme A, which is derived from carbohydrates via pyruvic acid. Animals also synthesize acetyl coenzyme A from amino acids.

A distinction is made between *de novo synthesis* of saturated fatty acids and *elongation* of a fatty acid chain. De novo synthesis leads primarily to palmitic acid with smaller amounts of lauric, myristic, and stearic acids.

De novo synthesis:

$$\underset{\text{Acetyl CoA}}{CH_3COSCoA} \xrightarrow{+CO_2} \underset{\text{Malonyl CoA}}{HOOCCH_2COSCoA} \xrightarrow[-HSCoA]{+CH_3COSCoA}$$

$$CH_3COCH(COOH)COSCoA \xrightarrow{-CO_2} CH_3COCH_2COSCoA$$

$$\xrightarrow{+H_2} CH_3CH(OH)CH_2COSCoA \xrightarrow{-H_2O}$$

$$CH_3CH{=}CHCOSCoA \xrightarrow{+H_2}$$

$$\underset{\text{Butyryl CoA}}{CH_3CH_2CH_2COSCoA} \xrightarrow[-HSCoA]{+\text{Malonyl CoA}}$$

$$CH_3CH_2CH_2COCH(COOH)COSCoA \text{ etc.}$$

The conversion of palmitic into stearic acid and the formation of longer chain saturated and unsaturated fatty acids presumably takes place by elongation, which involves addition of acetyl coenzyme A to activated fatty acids (RCOSCoA).

Elongation:

$$RCOOH \xrightarrow[-H_2O]{+HSCoA} RCOSCoA \xrightarrow[-HSCoA]{+CH_3COSCoA}$$

$$RCOCH_2COSCoA \longrightarrow \longrightarrow RCH_2CH_2COOH$$

The synthesis of fatty acids from C_2 units explains the predominance of even-numbered fatty acids in naturally occurring oils and fats. Bacterial degradation of feed in the rumen leads not only to acetic and butyric acids but also to propionic acid (C_3); incorporation of these C_3 units into fat synthesis in the udder explains the occurrence of branched and odd-numbered fatty acids in milk fat.

Oleic acid appears to play a key role in plants. It is probably synthesized from short-chain fatty acids and can be dehydrogenated into more highly unsaturated fatty acids; be converted into substituted acids such as ricinoleic acid; or elongated into erucic acid by specific enzyme systems (Fig. 1).

In the animal organism oleic acid is formed by dehydrogenation of stearic acid. Further dehydrogenation to linoleic and linolenic acid does not take place. The animal organism can, however, further desaturate linoleic and linolenic acid by introducing double bonds between the carboxyl group and the double bond nearest to it. Together with an elongation of the fatty acid chain this leads to the formation of γ-dihomolinolenic acid ($C_{20:3}$), arachidonic acid ($C_{20:4}$), and eicosopentaenoic acid ($C_{20:5}$), which are precursors of prostaglandins.

Three activated fatty acids (RCOSCoA) react successively with a molecule of phosphorylated glycerol to form a triglyceride molecule. The factors that determine the distribution of the fatty acids over the 1-, 2-, and 3-positions of the glycerides are not fully known. Phosphatides are also synthesized by this route.

Biodegradation. During digestion and absorption of fats, triglycerides are successively split into di- and monoglycerides, glycerol, and fatty acids by lipases. The products are absorbed by the intestinal epithelial cells either as water-soluble complexes or as micelles. The fatty acids are biodegraded mainly via β-oxidation:

Figure 1. Unsaturated fatty acids derived from oleic acid

The bio-oxidation of unsaturated fatty acids involves additional steps.

2.3. Phospholipids [20]

Phospholipids are essential constituents of the protoplasm of animal and plant cells; they are mostly present as lipoproteins and lipidcarbohydrate complexes. Oilseeds, cereal germs, egg yolk, and brain are the richest sources of phospholipids. Esters of glycerophosphoric acid (glycerol 1-phosphate) are usually referred to as phosphatides (→ Lecithin).

Some important phosphatides are phosphatidylcholine [*8002-43-5*] (lecithin), phosphatidylethanolamine [*5681-36-7*] (cephalin), phosphatidylinositol [*2816-11-7*], and phosphatidylserine.

The plasmalogens are ethers of fatty alcohols and phosphatidic acid; they occur in animal tissue.

Sphingolipids are derivatives of the amino alcohol sphingosine. For example, sphingomyelins are constituents of the phospholipids in the brain, blood plasma, and erythrocytes.

The cerebrosides are derivatives of sphingosine and either galactose (galactolipids) or glucose (glycolipids). They are important con-

stituents of the myelin nerve sheath. The gangliosides are based on neuraminic acid and are found in the ganglia cells of the brain.

Lecithin, cephalin, inositol phosphatides, and phosphatidic acid are the principal phospholipid components of plant origin. During pre-refining of crude vegetable oils, especially soybean and rapeseed oil, most of the phosphatides are removed as sludge by hydration with water. Drying of this sludge yields "lecithin," which is used, often after further modification, in the food industry as an emulsifier, antispattering agent, dispersant, or viscosity reducing agent. Lecithin is also used in pharmaceuticals, toiletries, animal feeds, and as a mold release agent and emulsifier – dispersant [21]. The phosphatide contents of crude oils and fats are listed in Table 3; the phosphatides are almost completely removed during refining of oils and fats.

2.4. Waxes

Waxes are esters of fatty alcohols and fatty acids (→ Waxes). Free and esterified fatty alcohols (e.g., cetyl, stearyl, oleyl alcohols) occur in considerable concentrations in marine oils. Ethers of glycerol and fatty alcohols (batyl, chimyl, and selachyl alcohols) are also found in animal tissues. The wax in the seed coat of sunflower seed causes the oil to become cloudy at refrigerator temperatures and is therefore removed by winterization (see Chap. 7).

2.5. Sterols and Sterol Esters

The major part of the nonsaponifiable matter of oils and fats consists of sterols present as such or as fatty acid esters and glycolipids. The most important sterol in animal fats is cholesterol [*57-88-5*]. β-Sitosterol [*83-46-5*] is the predominant sterol in vegetable oils and fats, although traces of cholesterol are also present. Total sterol concentrations are shown in Table 3, and sterol compositions in Table 4. Some of the sterols are removed during the deodorization step of refining oils and fats, without, however, changing their relative composition. Sterols are therefore a useful tool in checking authenticity. Vitamin D_2 [*50-14-6*] (calciferol) is present in milk and butter, and vitamin D_3 [*67-97-0*] (cholecalciferol) in cod liver oil. Other animal and vegetable oils contain hardly any vitamin D.

2.6. Terpenoids

The nonsaponifiable part of most fats also contains traces of terpenes and terpene alcohols. The triterpene squalene [*7683-64-9*] occurs in relatively high concentrations (up to 0.5 %) in olive oil. Shea butter contains 2 – 10 % of kariten, a rubber-like hydrocarbon.

Carotenoid pigments occur widely in oils and fats. Approximately 70 different carotenoids, ranging in color from yellow to deep red, are known. The most well-known carotenoids are the isomeric tetraterpenes ($C_{40}H_{56}$) α-carotene [*7488-99-5*], β-carotene [*7235-40-7*], and γ-carotene [*472-93-5*], lycopene [*502-65-8*], and xanthophyll [*127-40-2*]. Crude palm oil contains up to 0.2 % α- and β-carotene.

The bulk of the carotenoids are removed during refining, primarily during bleaching and deodorization. β-Carotene (provitamin A) can be oxidized to vitamin A [*68-26-8*] in the animal organism. Most vegetable oils and fats do not contain significant concentrations of vitamin A; in most countries margarine therefore contains added vitamin A. Vitamin A is present in high concentrations in fishliver oils. Butter contains ca. 0.003 – 0.0015 % vitamin A.

The most important compounds of the vitamin E [*59-02-9*] group are α-, β-, γ-, and δ-tocopherols:

	R^1	R^2	R^3
α-Tocopherol	CH_3	CH_3	CH_3
β-Tocopherol	CH_3	H	CH_3
γ-Tocopherol	H	CH_3	CH_3
δ-Tocopherol	H	H	CH_3

These compounds act as a vitamin (rat fertility factor) and as antioxidants. α-Tocopherol has the highest biological activity.

Tocopherols occur only in traces in animal fats, whereas vegetable oils contain appreciable concentrations (see Table 5). Refined oils and

fats still contain ca. 80 % of the original tocopherols, the main losses occurring during deodorization. Deodorizer distillates are a valuable source of natural tocopherols.

2.7. Other Minor Constituents

Sesame oil contains 0.3 – 0.5 % sesamolin [*526-07-8*], a glycoside of the phenol sesamol [*533-31-3*], and 0.5 – 2.0 % sesamin [*607-80-7*]. These minor constituents give a characteristic color reaction (the basis of the Baudouin test) and impart stability to oxidation.

Gossypol [*303-45-7*], a toxic polyphenol with pronounced antioxidant activity, is found in crude cottonseed and kapokseed oils (0.5 – 1.5 %). Gossypol is removed during refining in the lye neutralization step.

Crude linseed, rapeseed, soybean, olive, avocado, and many other vegetable oils contain the green pigments chlorophyll and phaeophytin. The chlorophyll content is particularly high in oil from immature seeds and is generally determined by harvesting and climatic conditions. Chlorophyll is generally regarded to be indicative of inferior crude oil quality; it can be removed by treatment with acidic absorbents such as bleaching earth.

Table 5. Tocopherols (mg/kg) in crude oils (main sources: Food RA, Leatherhead; Unilever; ITERG ** [22])

** ITERG = Institut des Corps Gras, Centre Technique Industrielle, Paris.

Crude oils and fats may contain traces of proteins, the concentration depending on processing conditions. In addition, vegetable oils may contain carbohydrates. These compounds are removed almost completely in refining.

Autoxidation of the fatty acid groups of triglycerides leads to the formation of volatile and nonvolatile oxidation products. The type and quantity of the volatile compounds (ketones, aldehydes, and alcohols) depend on the initial fatty acid composition and the oxidation conditions. These volatile products are responsible for the typical odor and taste of oils and fats. One of the main aims of refining is to remove these odoriferous compounds, which in some cases occur in concentrations of only 10^{-3} ppm. The nonvolatile oxidation products generally have little odor and taste, but they can act as oxidation promoters.

Most crude oils and fats contain traces of pesticide residues and metals (e.g., Fe, Cu, Pb, As, Cd, and Hg) as a consequence of crop treatment and environmental influences. Whereas phosphate-based pesticides used to treat oilseeds decompose with time, chlorinated pesticides are stable and gradually migrate into the oil.

Peanut oil may contain traces of aflatoxins produced by growth of *Aspergillus flavus* on the seed.

Most oils and fats, particularly coconut oil, contain varying concentrations of polycyclic aromatic hydrocarbons. These hydrocarbons are introduced during smoke-drying of the raw materials prior to storage and further processing.

Crude rapeseed oil contains up to 50 ppm of sulfur in the form of elemental sulfur, isothiocyanates, and 5-vinyl-2-oxazolidinethione [*500-12-9*] (goitrin) derived from glucosinolates (sulfur-containing glucosides) in the seed.

All of these undesirable contaminants are reduced to negligibly low levels in the course of refining, if necessary with the aid of additional steps such as adsorptive treatment with activated charcoal to remove polycyclic aromatic hydrocarbons.

Table 6. Melting points of fatty acids and glycerides in their stable polymorphic forms

	mp (slip point), °C

3. Physical Properties [23]

3.1. Melting and Freezing Points

The *melting point* of the even-numbered, saturated fatty acids increases with increasing chain-length, and decreases with increasing degree of unsaturation (see also → Fatty Acids, Chap. 2.1.). The glycerides show a similar behavior (Table 6). Since the naturally occurring fats are mixtures of glycerides, they melt over a wide range of temperature (for methods of melting point determination, see Section 11.3.1).

The melting point also depends on the polymorphic form of the glycerides, i.e., the crystalline structure (Table 7). The packing density and the spatial arrangement of the triglyceride molecules depend on the crystallization conditions. X-ray diffraction patterns (short spacing lines) can distinguish between three different polymorphic forms [25]. The lowest melting and most labile form is designated α. The most stable form is called β and the intermediate one β'. The α form is obtained by rapidly cooling the molten triglycerides, the β' form by suitable tempering. Polymorphic changes induced by processing conditions are of great practical importance since they can significantly influence the properties of, for example, a margarine (oral melting behavior, sandiness) or chocolate (fat bloom).

Table 7. Melting points of some polymorphic triglycerides

	mp, °C		
	α	β'	β

1-Lauro-2-myristo-3-stearin	27.5	45.5	49.5
1-Palmito-3-stearo-2-olein	18.2	33.0	38.0

The *congeal* or *set point* (point of solidification) is generally lower than the melting point.

Figure 2. Dilatation curves for cocoa butter and lard

The *solids content* of a fat at different temperatures is normally determined by pulsed nuclear magnetic resonance [24]. Fats exhibit an increase in volume (dilatation) on melting that is disproportionately larger than that on heating a liquid fat; an obsolete method of measuring solids content at different temperatures was based on dilatation. *Dilatation* or *solids content curves* can be used to characterize a fat. Figure 2 reflects the large proportion of 1-palmito-3-stearo-2-olein in cocoa butter and the more complex glyceride composition of lard.

The *latent heat of fusion* increases with increasing chain length and increasing degree of saturation (see Table 8). Naturally occurring fats generally have a lower heat of fusion than simple glycerides.

1-Palmito-2-capro-3-stearin	280	223
1-Capro-2-lauro-3-myristin	249	189

3.2. Thermal Properties

The approximate *heats of combustion* of oils and fats can be calculated from the following formula:

$$\begin{aligned}&\text{Heat of combustion (J/g)}\\&= 47645 - 4.1868 \times \text{iodine value}\\&\quad -38.31 \times \text{saponification value}\end{aligned}$$

Using this equation, values ranging from 37 765 J/g (9020 cal/g) for coconut oil to 40 528 J/g (9680 cal/g) for a high-erucic rapeseed oil have been obtained.

The *specific heat* of liquid oils and fats increases with increasing chain length and degree of saturation (see Table 9); it also increases with temperature.

Triglycerides of long-chain fatty acids have extremely low *vapor pressures*; typical data for some triglycerides and oils are shown in Table 10. Monoglycerides have significantly higher vapor pressures (see Table 11). There is relatively little information on the *heats of vaporization* of fats (see Table 12).

Table 11. Boiling points of some monoglycerides

	Pressure, Pa	*bp*, °C
Monocaprin	133.3	175
Monolaurin	133.3	186
Monomyristin	133.3	199
Monopalmitin	133.3	211
Monostearin	26.7	190
Monoolein	26.7	186

Table 12. Heat of vaporization of some triglycerides calculated for 0.13 – 67 Pa

	Heat of vaporization, J/g
Tricaprylin	247.0
Tricaprin	226.1
Trilaurin	213.5
Trimyristin	205.2
Tripalmitin	201.0
Tristearin	188.4
Soybean oil	209.3

Oils and fats are relatively poor thermal conductors. Data for *thermal conductivity* are limited. Most data lie within ± 10 % of the following general relationship:

$$\text{Thermal conductivity } \left(\mathrm{W\,m^{-1}K^{-1}}\right) = 0.181 - 0.00025t$$

where t = temperature in °C.

The *smoke, flash,* and *fire points* of oils and fats are measures of their thermal stability when heated in air (Table 13).

3.3. Density

The density of fatty acids and glycerides decreases with increasing molecular mass and degree of saturation (Tables 14 and 15). Oxidation generally leads to higher densities. A high free fatty acid content tends to decrease the density of a crude oil. The following formula can be used to estimate the density of an oil:

$$d_{15}^{15} = 0.8475 + 0.0003 \times \text{saponification value} + 0.00014 \times \text{iodine value}$$

Up to 260 °C the density decreases by about 0.00064 g/cm^3 per temperature increase of 1 °C. The following equations apply for the density ϱ (in g/L) of commercial oils and fats (t = temperature in °C):

Soybean oil	$933.4 - 0.657\,t$
Sunflower oil	$932.7 - 0.680\,t$
Sesame oil	$933.0 - 0.700\,t$
Cottonseed oil	$931.7 - 0.755\,t$
Peanut oil	$927.0 - 0.642\,t$
Olive oil	$928.5 - 0.700\,t$
Palm oil	$925.0 - 0.655\,t$
Palm kernel oil	$940.0 - 0.740\,t$
Coconut oil	$932.0 - 0.745\,t$
Rapeseed oil	$925.5 - 0.700\,t$
Tallow	$956.8 - 0.898\,t$
Fish oil	$940.0 - 0.700\,t$

3.4. Viscosity

Oils tend to have a relatively high viscosity because of intermolecular attraction between their fatty acid chains. Generally, viscosity tends to increase slightly with increasing degree of saturation and increasing chain length (see Tables 16 and 17). There is an approximately linear relationship between log viscosity and temperature. The viscosity of oils tends to increase on prolonged heating due to the formation of dimeric and oligomeric fatty acid groups.

3.5. Solubility and Miscibility

Nearly all fats and fatty acids are easily soluble in common organic solvents such as hydrocarbons, chlorinated hydrocarbons, ether, and acetone. Castor oil is an exception in that it is only partially soluble in petroleum ether but easily so in ethanol. The solubility of fatty acids in ethanol is greater than that of the corresponding triglycerides. The solubility of fats in organic solvents decreases with increase in molecular mass and increases with degree of unsaturation.

Table 13. Smoke, flash, and fire points of refined oils and fats

	ffa ∗, %	Smoke point, °C	Flash point, °C	Fire point, °C
Rapeseed oil	0.08	218	317	344

Beef tallow	0.4		316	344
Beef tallow	5.0		266	344

∗ ffa = free fatty acid.

The differences in solubility enable categories of glycerides to be separated by fractional crystallization although complete separation is rarely achieved because of mutual solubility effects.

The water solubility of fats is low and decreases with increasing chain length and with decreasing temperature. The solubility of water in cottonseed oil is, for example, 0.14 wt % at 30 °C and 0.07 wt % at 0 °C.

The solubility of gases in oils generally increases with increase in temperature, the reverse holding for carbon dioxide (Table 18).

3.6. Surface and Interfacial Tension

The surface and interfacial tensions of some oils are shown in Table 19. The interfacial tension is markedly reduced by the presence of surface-active agents, e.g., phosphatides, monoglycerides, free fatty acids, and soaps.

Table 19. Surface and interfacial tension of some oils

	Surface tension, mN/m			Interfacial tension
	20 °C	80 °C	130 °C	at 70 °C, mN/m
Cottonseed oil	35.4	31.3	27.5	29.8
Coconut oil	33.4	28.4	24.0	
Castor oil	39.0	35.2	33.0	
Peanut oil				29.9
Soybean oil				30.6

3.7. Electrical Properties

Dry oils, fats, and fatty acids are poor conductors of electricity. Recorded values for the specific resistance of stearic acid are $0.6\times10^{11}\,\Omega$ at 100 °C and $22.3\times10^{11}\,\Omega$ at 186 °C, and for oleic acid 2×10^{11} and $83\times10^{11}\,\Omega$ at comparable temperatures. The dielectric constant of most oils lies in the range 3.0 – 3.2 at 25 – 30 °C. Castor and oiticica oil have dielectric constants of about 4 in this temperature range because of the hydroxyl and keto groups in the fatty acid chains. In emulsion systems, e.g., butter or margarine, the dielectric constant is affected by both the emulsion structure and the moisture content.

3.8. Optical Properties

The refractive index of oils, fats, and fatty acids generally increases with increasing chain length, number of double bonds, and extent of conjugation (see Tables 20 and 21). The refractive index of fatty acids is much lower than that of the corresponding triglycerides. Prolonged heating leads to an increase in refractive index due to the introduction of polar groups into the fatty acid chain.

∗ n^{40}.

There are a number of equations depicting a relationship between refractive index and other data. The following equation has been suggested for fresh, nonhydrogenated oils and fats:

$$n_D^{40} = 1.4643 - 0.00066 \times \text{saponification value} - \frac{0.0096 \times \text{acid value}}{\text{saponification value}} + 0.0001711 \times \text{iodine value}$$

Pure glycerides do not absorb in the visible region of the spectrum (400 – 750 nm). However, naturally occurring oils and fats invariably contain pigments that have characteristic absorption bands (carotene at 450 nm, chlorophyll and phaeophytin at 660 nm). Most of these pigments are removed during refining. Unsaturated oils and fats absorb in the ultraviolet region between 200 and 400 nm. Conjugated double bonds show characteristic maxima at 232 nm (dienes, e.g., 9,11-*trans,trans*-linoleic acid) and at 268 nm (trienes, e.g., β-eleostearic acid). Conjugated tetraenoic acids absorb between 290 and 320 nm.

In the infrared region (0.075 – 1000 µm) chain substituents such as epoxy, hydroxyl, keto, and cyclopropene groups as well as trans double bonds exhibit specific absorption peaks:

monoglycerides	1.43 µm
hydroxy fatty acids	3.20 µm
ester carbonyl group	5.83 µm
trans double bonds	10.0 – 10.35 µm
isolated trans double bonds	10.35 µm

The fingerprint region around 8 µm can be used to determine the fatty acid chain length.

X-ray spectroscopy is employed to characterize the various polymorphic crystal structures of pure glycerides (see Section 3.1).

Nuclear magnetic resonance of hydrogen atoms is used in structural identification and to determine the solids content of fats at different temperatures. Nuclear magnetic resonance measurement of phosphorus and nitrogen atoms can be employed to analyze the composition of phosphatide mixtures.

The optical activity of enantiomorphic triglycerides with different fatty acid groups in the 1- and 3-positions is usually too small to be measured [20].

4. Chemical Properties

The chemical reactions of fats are basically those of esters and hydrocarbon chains (→ Esters, Organic). Only those reactions that are primarily relevant to the processing of edible oils and fats are dealt with in this chapter.

4.1. Hydrolysis

Glycerides can be hydrolyzed into fatty acids and glycerol:

$$\begin{array}{l} CH_2OCOR \\ | \\ CHOCOR + 3H_2O \rightleftharpoons \\ | \\ CH_2OCOR \end{array} \quad \begin{array}{l} CH_2OH \\ | \\ CHOH + 3RCOOH \\ | \\ CH_2OH \end{array}$$

The reaction is reversible; in practice the equilibrium can be shifted to the right by using a large excess of water, high temperatures, and high pressures.

Hydrolysis is catalyzed by inorganic and organic acids, e.g., sulfonated hydrocarbons. In the enzymatic hydrolysis of glycerides with pancreatic lipase, the fatty acid groups in the 1- and 3-positions, are split off preferentially.

A fat can also be hydrolyzed with alkali (saponification, see also → Soaps):

$$\begin{array}{l} CH_2OCOR \\ | \\ CHOCOR + 3NaOH \longrightarrow \\ | \\ CH_2OCOR \end{array} \quad \begin{array}{l} CH_2OH \\ | \\ CHOH + 3RCOONa \\ | \\ CH_2OH \end{array}$$

4.2. Interesterification

Like other esters, glycerides can be transesterified by acidolysis or alcoholysis (→ Esters, Organic, Chap. 3.2.). In the presence of an alkaline catalyst and an excess of glycerol, triglycerides form a mixture of mono- and diglycerides (alcoholysis).

The acyl groups of glycerides can also be exchanged inter- and intramolecularly without addition of acids or alcohols (interesterification).

$$\begin{array}{l} CH_2OCOR^1 \\ | \\ CHOCOR^1 \\ | \\ CH_2OCOR^1 \end{array} + \begin{array}{l} CH_2OCOR^2 \\ | \\ CHOCOR^2 \\ | \\ CH_2OCOR^2 \end{array} \rightleftharpoons$$

$$\begin{array}{l} CH_2OCOR^2 \\ | \\ CHOCOR^1 \\ | \\ CH_2OCOR^1 \end{array} + \begin{array}{l} CH_2OCOR^1 \\ | \\ CHOCOR^2 \\ | \\ CH_2OCOR^2 \end{array} \rightleftharpoons \text{etc.}$$

Even at 200 – 300 °C interesterification proceeds very slowly, but the reaction can be accelerated by using an alkaline catalyst such as a metal alkoxide. With such a catalyst the reaction is complete within one minute at 80 °C. Interesterification is of practical importance since it enables the physical properties of a fat, e.g., melting behavior and consistency, to be modified without changing the fatty acids chemically, as occurs in hydrogenation (hardening).

Interesterification may be either random or directed. *Random interesterification* leads to a random distribution of the fatty acid groups over the triglyceride molecules. This is demonstrated for interesterification of equal proportions of tristearin (S – S – S) and triolein (O – O – O):

$$\begin{array}{ll} S-S-S & + \; O-O-O \\ 50\% & \quad 50\% \end{array}$$

$$\downarrow$$

$$\begin{array}{cccccc} S-S-S & S-O-S & O-S-S & S-O-O & O-S-O & O-O-O \\ 12.5\% & 12.5\% & 25\% & 25\% & 12.5\% & 12.5\% \end{array}$$

S = stearic acid, O = oleic acid

In *directed interesterification*, the temperature is reduced to such an extent that the highest melting glycerides are continously frozen out of the reaction mixture, in turn continuously shifting the reaction equilibrium. In this way a fat can be separated into higher and lower melting fractions. The higher melting fraction contains the glycerides of saturated fatty acids (stearin fraction), whereas the glycerides of unsaturated fatty acids are found in the lower melting fraction (olein fraction). Directed interesterification of stearodiolein can yield 33.3 % of tristearin and 66.7 % of triolein:

$$O-S-O$$

$$\downarrow$$

$$\begin{array}{ll} S-S-S & O-O-O \\ 33.3\% & 66.7\% \end{array}$$

S = stearic acid, O = oleic acid

4.3. Hydrogenation

The double bonds in a fatty acid chain can be wholly or partially saturated by addition of hydrogen in the presence of a suitable catalyst such as nickel, platinum, copper, or palladium. Hydrogenation always leads to an increase in melting point and is therefore also called "hardening". Partial hydrogenation can lead to isomerization of cis double bonds to trans double bonds.

The catalyst, the oil, and the hydrogen must be brought into mutual contact under suitable

temperature and pressure conditions. The reaction rate depends on mixing intensity, the type of oil or fat, temperature, catalyst activity, and concentrations of catalyst and dispersed hydrogen. Hydrogenation is an exothermic process. Industrial nickel catalysts are generally obtained by precipitation of nickel hydroxide or carbonate on kieselguhr, silica gel, alumina, or similar carriers, followed by reduction to metallic nickel, or by in situ production of metallic nickel from nickel formate. Such heterogeneous catalysts have a large activated surface. During hydrogenation the double bonds form transient complexes with the active centers of the catalyst. These complexes disintegrate after reaction of the double bonds with hydrogen, leaving the catalyst in its original form [26]. The active centers of the catalyst can be inactivated or poisoned by a number of compounds such as phospholipids, sulfur compounds, organic acids, and oxidized lipids.

A fatty acid with several double bonds, such as linolenic acid ($C_{18:3}$), is hydrogenated more quickly to linoleic acid ($C_{18:2}$) or oleic acid ($C_{18:1}$) than is linoleic acid to oleic acid or oleic acid to stearic acid ($C_{18:0}$). The reaction sequence occurring during hydrogenation can be represented schematically as follows:

$$C_{18:3} \xrightarrow[+H_2]{k_1} C_{18:2} \xrightarrow[+H_2]{k_2} C_{18:1} \xrightarrow[+H_2]{k_3} C_{18:0}$$

The term selectivity is used to indicate which of these reactions is fastest. Selectivity I is defined as the ratio k_2/k_3; it is related to the proportion of saturated glycerides formed and to the melting behavior of the product. Selectivity II, expressed as the ratio k_1/k_2, must be as high as possible if the concentration of linoleic acid in the hydrogenated product is to be maximized [27].

Selectivity can be influenced by the catalyst type (surface area, pore size, etc.) and by altering the reaction conditions. An increase in selectivity, i.e., an increase in partial hydrogenation, promotes isomerization of cis to trans double bonds.

At temperatures above 200 °C and with a low hydrogen concentration, catalytic hydrogenation of polyunsaturated fatty acid groups can lead to the formation of traces of cyclic aromatic compounds [28].

The double bonds of substituted fatty acids such as ricinoleic acid can also be hydrogenated under suitable reaction conditions. Cyclopropane or cyclopropene groups behave as double bonds and lead to branched fatty acids on hydrogenation.

Iron pentacarbonyl and cobalt octacarbonyl are examples of homogeneous hydrogenation catalysts.

Reduction with hydrazine does not lead to isomerization; there is also no selectivity ($k_1 = k_2 = k_3$).

4.4. Isomerization

Naturally occurring fatty acids exist predominantly in the cis form. An equilibrium mixture in which the higher melting trans form predominates can be formed by heating to 100 – 200 °C in the presence of catalysts such as nickel, selenium, sulfur, iodine, nitrogen oxides, or sulfur dioxide.

If selenium or oxides of nitrogen and sulfur are used in the cis – trans isomerization (elaidinization) of oleic acid, there is virtually no positional isomerization. However, cis – trans isomerization of linoleic and linolenic acid leads to conjugated double bonds.

Nonconjugated systems can be isomerized into conjugated systems by heating in an alkaline solution at 200 °C (→ Fatty Acids, Chap. 2.1.). If reaction times and temperatures are extended, linolenic acid can be converted into cyclohexadiene and benzene derivatives:

Isomerization can occur if oils and fats are heated at temperatures above 100 °C in the presence of bleaching earth, kieselguhr, or activated charcoal.

4.5. Polymerization

Dimeric, oligomeric, and polymeric compounds are formed by heating unsaturated fatty acids at 200 – 300 °C [29]. The rate of polymerization increases with increasing degree of unsaturation; saturated fatty acids cannot be poly-

merized. Thermal polymerization of polyunsaturated fatty acid groups is normally preceded by isomerization and conjugation of double bonds. Thermal polymerization involves formation of new carbon–carbon bonds by combination of acyl radicals and by Diels–Alder reactions, while oxidative polymerization involves formation of C–O–C bonds. Thermal dimerization is catalyzed by Lewis acids such as boron trifluoride; industrial processes for dimerizing oleic acid are based on this principle [30]. Heating of oils during refining or during household use does not lead to a significant increase in dimeric triglycerides. Up to 2 % dimeric triglycerides can be encountered in fresh raffinates; these dimers are not toxic, and are largely excreted as such.

4.6. Autoxidation

Autoxidation, the oxidation of olefins with oxygen, plays a decisive role in the development of rancidity, off-flavors, and reversion flavors in oils and fats during their production and storage. Autoxidation of oil-containing products such as oilseeds and spent bleaching earths can lead to their spontaneous combustion. Autoxidation of drying oils is an important initial stage of polymerization leading to stable surface films (→ Drying Oils and Related Products, Chap. 3.).

Autoxidation involves the formation of a hydroperoxide on a methylene group adjacent to a double bond; this step proceeds via a free-radical mechanism:

Autoxidation is characterized by an induction period during which free radicals are formed. This phase is triggered by light (photooxygenation), heat, and the presence of compounds that readily form free radicals (e.g., hydroperoxides, peroxides, and transition metals). Photooxygenation, i.e., light-induced oxidation, leads to a particularly fast buildup of radical concentration. The formation of singlet oxygen under the influence of short-wave radiation and a sensitizer such as chlorophyll or erythrosine probably plays a key role in this reaction.

The reactivity of a methylene group in forming a hydroperoxide is enhanced by a second adjacent double bond. Hence linoleic acid oxidizes 10 to 20 times faster than oleic acid. Linolenic acid reacts about three times faster than linoleic acid, since two doubly activated methylene groups are present. The olefin radical formed subsequently isomerizes; in a 1,4-diene such as linoleic acid, isomerization leads to conjugated hydroperoxides:

The intermediate hydroperoxides are labile compounds that decompose into a number of different products: epoxides, alcohols, diols, keto compounds, dicarboxylic acids, aldehydes, and isomerization and polymerization products. The volatile carbonyl compounds formed in this process are responsible for the taste and odor of oxidized oils and fats.

When the radical concentration has reached a certain limit, the chain reaction is gradually stopped by mutual combination of radicals.

Antioxidants prolong the induction period by reacting with the intermediate products of the chain reaction, forming inactive radicals. Tocopherols are naturally occurring antioxidants. Butylhydroxyanisole (BHA), butylhydroxytoluene (BHT), and propyl gallate are among the most effective synthetic antioxidants (→ Antioxidants). Certain organic or inorganic acids (citric, tartaric, ascorbic, phosphoric acids) have a synergistic effect without being true antioxidants; this effect is presumably based on the inactivation of trace metals or reduction of oxidized antioxidants.

5. Manufacture and Processing

Oils and fats are either of vegetable or animal origin. The approximate proportions of the corresponding world production are 55 % vegetable oils, 40 % land-animal fats, and 5 % marine oils.

5.1. Vegetable Oils and Fats

5.1.1. Storage and Handling of Raw Materials

The handling of oleaginous seeds and fruits during transport and storage has a decisive influence on the quality of the crude oils. The oils in fruit pulp (e.g., olive and palm) are very susceptible to enzymatic hydrolysis since they are finely dispersed in moist cell tissue. The oils contained in seeds are more stable but can also be attacked. A high moisture content accelerates the uptake of oxygen and the corresponding release of carbon dioxide due to degradation of starch. The heat generated in this reaction promotes lipolysis, growth of microorganisms (which can lead to the formation of mycotoxins such as aflatoxins), formation of undesirable color and odor, and – in extreme cases – may result in a coagulation of seed in a silo and even spontaneous combustion [31], [32]. Damage of seed cells, mechanically or by pests, also promotes lipolysis and lipoxidation. Free fatty acids, oxidation products, and coloring matter formed by lipolysis, lipoxidation, and degradation of protein and carbohydrate can in general be removed from the oil only with difficulty, with corresponding yield losses.

In order to minimize these effects, oilseeds must be dried before storage, preferably under mild conditions to avoid cellular damage. The critical moisture content roughly correlates with the hygroscopic equilibrium at 75 % relative humidity and varies between 6 and 13 %, depending on the protein and carbohydrate content. In the case of copra, rapeseed, and sunflower seed, the critical moisture content is 7 %; in the case of soybeans 13 %.

Transport and handling in bulk has almost entirely superseded that in bags. Seed is normally stored in concrete silos that are ventilated to avoid local generation of heat and water pockets; such silos can be up to 70 m in height and up to 12 m in diameter. The silos are filled from the top, emptied from the bottom, and normally equipped with special vibrating devices at the bottom to minimize bridging.

5.1.2. Cleaning and Dehulling

On arrival at the oil mill, oilseeds still contain plant residues, dust, sand, wood, pieces of metal, and foreign seed, which must be removed prior to further processing by screening, air classification, and passage over magnets.

Some oilseeds are dehulled (decorticated) before being further processed, especially if only the oil is to be expelled, since the hulls tend to retain part of the oil. Preexpelling and subsequent extraction with solvents is the most common process; a certain proportion of hulls in the material to be extracted can be desirable since they facilitate percolation. An excessively high proportion of hulls can, however, impair the quality of the crude oil since the solvent also dissolves wax from the seed coat. A further reason for dehulling can be the need to produce so-called high protein meal, for example from soybeans.

Dehulling is normally preceded by relatively intense drying of the seed material to help loosen the seed coat from the meats. Dehulling is normally performed by using impact disintegration or passage through rolls to break up the seeds. The hulls are separated by screening and air-classification.

5.1.3. Expelling

Modern processing of oilseeds generally involves a combination of expelling and solvent extraction. Seed is normally preexpelled to a residual fat content of ca. 20 %, and the expeller cake is then extracted to 1 – 2 % fat. Preexpelling is omitted if the fat content of the seed is 20 % or less. High-pressure expelling down to ca. 4 % residual fat is no longer important, mainly because of the higher processing costs.

Most of the fat present in seeds and fruit pulp is in the endosperm and hypocotyl cells, with much less in the seed coat. The processing conditions are largely determined by the size and stability of the oil-containing cells. With palm fruit and olives, mere heating or boiling with

water suffices to burst the membranes of the oil-containing cells to liberate the oil. Nearly all oleaginous seeds must, however, first be comminuted and thermally pretreated to isolate the fat in an acceptable yield. Comminution partially destroys the cellular structure, increasing the total internal surface and facilitating access to the oil within the seed.

Coarse materials such as copra are first broken by passage through interlocking rolls. Fluted rolls are used for nearly all other seeds. Smooth or so-called flaking rolls are used to complete seed comminution. These three types of rolls are shown in Figure 3; they can be arranged in parallel, diagonally, or sequentially. In the more modern, parallel arrangement, the rotational speed of the two rolls differs by 5 – 10 % to produce an additional shear effect. The separation of the rolls and their circumferential speed is adjusted to the type of seed and the degree of cell rupture required for the subsequent expelling and extraction.

Figure 3. Schematic representation of various rolls used for expelling oilseeds
A) Side view; B) Top view

The comminuted seed is conditioned prior to expelling by moistening and heating in suitable equipment. During this treatment lipoproteins decompose, proteins coagulate, and intracellular oil bodies coalesce. The cell walls themselves are not macerated during conditioning. Coagulation of protein facilitates expelling and subsequent percolation in the extractor. Undesirable enzymes and microorganisms are deactivated at temperatures above 80 °C and in the presence of sufficient moisture [33].

By suitably conditioning cottonseed, the toxic gossypol can be deactivated by association with denatured protein. In rapeseed, suitably severe conditioning deactivates the enzyme myrosinase and hence improves the quality of the meal and the oil. However, excessive heating impairs the nutritive quality of the expeller cake as well as the color and taste of the expeller oil and must be avoided. An excessively high moisture content can reduce the yield of expeller oil. Each type of seed must therefore be adjusted to an optimal moisture content and temperature during conditioning.

Figure 4. Vertical stack cooker for conditioning oilseeds (Krupp)
a) Level control; b) Steam heating; c) Insulation; d) Steam jet; e) Manhole; f) Steam heating; g) Sweep stirrer

Conditioning is performed in horizontal jacketed tubes (conditioners) or in vertical stack cookers. The stack cooker basically consists of up to five kettles arranged in a tier and through which the seed material successively moves from the top to the bottom; each kettle is equipped with a sweep stirrer and facilities for direct and indirect steam heating (Fig. 4). Generally, wet cooking with direct steam takes place in the top kettle, and drying, with increased temperatures and venting, in the bottom kettles.

Expelling (pressing) separates the oil from the solid phase, the so-called expeller cake, and

can be done in continuous or batch presses. Levers, wedges, or screws were used to apply pressure in the more primitive types of batch presses, but modern batch presses are almost invariably operated by a hydraulic system. They can be divided into the open type, in which the seed must be wrapped in press cloths, and the closed type, which dispenses with press cloths and confines the material in a cage-type construction. Open-type presses can be subdivided into plate and box presses, closed types into pot and cage presses.

Continuous expellers or screw presses (e.g., Simon – Rosedowns, Krupp) have generally replaced batch presses. Deoiling in these presses is efficient and uniform since the layer of material to be expelled is relatively thin and is continuously broken up. Several types exist, all with the common principle of a worm shaft rotating in a cylindrical drainage barrel (Fig. 5). The barrel is composed of armored, rectangular bars that fit into the barrel bar frame. The individual bars are separated by bar spacing clips, the specific spacings – ranging from 0.1 to 0.4 mm – depending on the type of seed and degree of expelling required. The required pressure is built up either by a gradual increase in the diameter of the worm shaft or by a gradual restriction of the barrel diameter. Specific pressure profiles and cake thickness can be further controlled by variations in the pitch of the worm and choke mechanisms in the barrel. The expelled oil is discharged through the barrel spacings while the expeller cake emerges at the end of the barrel.

Figure 5. Screw press (Krupp)
a) Drainage barrel; b) Worm shaft

The capacity of screw presses varies widely, being dependent primarily on the cross-sectional ratio and the speed of the screw. The pressure should be built up fairly slowly. Initially, the channels in the expeller cake are sufficiently large for ready discharge of oil; in the latter sections of the screw press, the pressure is increased to about 300 MPa (3000 bar) to expel more tightly bound oil and to burst intracellular oil bodies.

Up to 200 t of seed per day per press is normally preexpelled to a residual fat content of 15 – 25 %. The expeller cake is then comminuted on fluted rolls, and possibly also pelletized, prior to solvent extraction.

Screw presses used to reduce the residual fat content to 3 – 6 % are similar in design to preexpellers but have a larger compression ratio (1 : 25 instead of 1 : 15) and have a lower worm speed (9 – 12 rpm versus 30 – 45 rpm).

A specific worm arrangement normally gives optimal results for only one particular type of seed. Difficulties encountered on changing the type of seed can often be overcome by modifying conditioning and comminution. Preexpellers that do not require seed conditioning of sunflower seed have been developed; however, they do not work as well with unconditioned rapeseed.

The expeller oil still contains so-called foots, which must be removed by filtration.

5.1.4. Extraction [34], [35]

Very much lower residual fat contents can be achieved by solvent extraction than by expelling. Seed material with an oil content of ca. 20 % and expeller cake with 15 – 25 % fat are usually subjected to solvent extraction. Both must be flaked prior to extraction. This pretreatment creates a large internal surface and yields thin (ca. 0.3 mm), firm flakes, which form a loose layer in the extractor and provide uniform, short diffusion pathways. The flakes must have a minimum moisture content and elasticity to prevent them from crumbling during transport to the extractor, which would lead to too dense a packing and hence poor percolation of solvent. However, a high moisture content also impairs percolation.

Ideally, the extraction solvent should dissolve only glycerides but not undesirable components such as coloring matter, gums, and phospholipids. The solvents must not contain toxic components, and should be recoverable with minimum loss, be safe in handling, and be readily removable from the extracted material. For these reasons aliphatic hydrocarbons, especially

hexane, are used almost exclusively. Technical hexane with a boiling point range of 55 – 70 °C has proved to be optimal. Hexane can be readily removed from the oil at temperatures below 100 °C in vacuo and can be stripped from the meal with steam. The solubility of hexane in the condensed water is only 0.1 %.

For special purposes, e.g., the production of heat-labile pharmaceuticals, lower-boiling hydrocarbons such as pentanes are sometimes used. Extraction with propane or carbon dioxide under supercritical conditions is reserved for special products of high intrinsic value because of the high equipment costs involved. Castor oil, being relatively polar, is preferably extracted with the higher-boiling heptane. Alcohols (methanol, ethanol, propanol, and butanol) and furfural are specially suited for the extraction of relatively wet materials. Extraction of oilseeds with alcohols leads to relatively high concentrations of phosphatides, glycolipids, carbohydrates, and similar constituents in the crude oil, although the glycerides can in principle be concentrated by cooling or extraction of the alcoholic solutions. Alcohols are generally not used as primary extraction solvents. However, they are occasionally used as secondary extraction solvents to remove gossypol from cottonseed meal, thioglycosides from rapeseed meal, sugars from soybean meal (to produce protein concentrates), and alkaloids from bitter lupine meal.

Chlorinated hydrocarbons such as trichloroethylene and dichloromethane are of interest because of their safety in handling and high extraction capacity but do not appear to be used for extraction of oilseeds because of the potential toxicity risk from residual solvent in the meal. Processes in which the oil is displaced by hot water are known but have not achieved industrial importance [36].

Oilseeds are generally extracted in a countercurrent process: pure solvent is contacted with material that has already been largely extracted, and the oil-rich solution is contacted with nonextracted material. Such extractions can be performed either continuously or in a batch process.

Batch processes. In a discontinuous process the solvent successively passes through a battery of up to batch extractors (e.g., from Buss). Each of these extractors is a cylindrical vessel with a large diameter : height ratio and has an opening for filling and emptying, a screen in the bottom part, and facilities for pumping solvent in and out, for direct and indirect steam heating, and a sweep stirrer to move the extracted meal during solvent stripping (desolventization) (Fig. 6).

Figure 6. Batch extractor
a) Stirrer; b) Screen

After filling the extractor with comminuted seed material, the upper opening is closed and solvent pumped in. The displaced air escapes via a circuit; the hexane vapors in the displaced air are recovered. After the extractor has been filled with solvent, the hexane containing the extracted oil is pumped into a second extractor filled with seed material. This process is repeated until the hexane solution has been pumped through 3 or 4 extractors. The solvent strongly enriched with oil (the miscella) from the last extractor is filtered to remove seed particles and then distilled. In this type of process, exhaustive extraction can yield oil concentrations of at least 35 % in the final miscella.

When the contents of the first extractor have been extracted sufficiently, the solvent tap is closed; the pure extraction solvent is then passed directly to the second extractor while the fifth extractor becomes part of the battery. After discharging the solvent, remaining solvent is stripped from the extracted seed material by passing in steam. When the vapors leaving the extractor are free of solvent, the extractor is emptied via the lower opening.

The sequence of filling, extraction, desolventization and emptying is repeated for each ex-

tractor in a battery in such a way that while one extractor is being filled, the contents of three or four extractors are extracted, residual solvent is stripped in one or two extractors, and one extractor is emptied.

The vapors from the extractors and the distillation are condensed. The resulting hexane – water mixture is separated mechanically and the hexane recycled. Such a battery with 10 extractors of 7 m^3 each can reach a daily throughput of up to 1200 t seed, depending on the type of seed. The quantity of hexane circulated is ca. 100 t. The solvent loss is normally between 0.35 and 0.45 %, based on seed input.

These discontinuous plants can be automated, and have the principal advantage that special treatment of meal (e.g., detoxification of aflatoxin-containing peanut or cottonseed meal with ammonia) can be carried out fairly easily. Their capacities cannot, however, match those of fully continuous plants, which can process up to 200 t seed per hour.

Continuous Processes. Of the many fully continuous processes that have been proposed and developed, countercurrent gravity percolation has become the most popular because of its high capacity. The comminuted seed material is transported through the extractor and sprayed with solvent in the various extraction stations. The solvent becomes increasingly enriched with oil and is passed through the seed bed repeatedly according to the number of extraction stations. This arrangement has the advantage that the miscella is continuously cleaned by filtration through the seed bed.

The MIAG basket conveyor extractor (Fig. 7) uses a horizontal arrangement of baskets in which the flaked seeds are first sprayed with solvent or miscella and then passed through a solvent bath. The baskets containing the extracted and drained flakes are automatically inverted and discharged into a hopper from which the meal is conveyed to the desolventizers and dryers.

In modern plants with a capacity of up to 5000 t of seed per day, circular cell and traveling belt horizontal extractors are generally preferred. The Blaw – Knox Rotocel extractor is especially popular because it offers a large capacity within a relatively small space. It uses baskets that travel in a horizontal circle. After countercurrent extraction, the baskets are emptied through hinged sieve bottoms.

Figure 7. MIAG basket conveyor extractor

The carousel extractor from Extraktionstechnik operates on a similar principle (Fig. 8), but has a fixed discharge point instead of movable basket bottoms.

Figure 8. Carousel extractor

In traveling belt extractors, such as the De Smet extractor, the seed material is conveyed on an endless sieve belt, the height of the bed being regulated mechanically. Miscella and solvent are sprayed onto the seed material. Miscella percolates throught the belt, falls into compartments in the bottom of the extractor housing, and is picked up by a series of pumps and recirculated countercurrent to the flakes.

The Lurgi frame belt extractor works on a similar principle [37]. The endless frame belt runs over two bar-sieve belts which form the bottoms of the frames. The flaked oilseeds are filled into the frames of the upper belt, tipped onto the lower belt after half the extraction time has elapsed, and then discharged after completion of extraction and passage through a dripping zone. This separation into distinct extraction steps and

intermediate decompaction effects a particularly uniform extraction.

There are numerous other types of extractors which are of less practical importance. In Hildebrandt, Schlotterhose, Ford, Detrex, Adler, and Olier extractors, the comminuted seed material is transported through a solvent bath by a screw; Figure 9 shows the principle involved. In a Kennedy extractor (Fig. 10), the material to be extracted is conveyed to various sections of a trough by means of impeller wheels. In the Sherwin – Williams process the finely comminuted seed material is thoroughly mixed with solvent in three stages and then separated centrifugally from the miscella. The structure of the seed material is not as critical for these extractors as for basket or belt-type extractors. However, they require a far greater ratio of solvent to seed material. Their miscella are also contaminated with fines, which requires a separate filtration step. These types of extractors are therefore virtually obsolete.

Figure 9. Screw extractor

Böhm, Tyca, Allis – Chalmers, Bonotto, and Anderson extractors are essentially columns divided into a number of sections in which the seed material moves from the top to the bottom, countercurrent to a rising flow of solvent. These extractors do not match the performance of the large basket or belt-type extractors.

Several attempts have been made to develop processes obviating preexpelling. In the Filtrex process, which is used to a limited extent, oilseeds such as rapeseed, sunflowerseed, or peanuts can be extracted directly to about 1 % residual fat without preexpelling, provided the seed material has been flaked to about 0.1 mm (the cell structure is probably destroyed) and subsequently conditioned by "crisping" [38]. A drawback is that emersion-type extractors are required. In the Direx process the seed material is only coarsely ground, extracted to 14 – 16 % residual fat with hexane, flaked, and then extracted to ca. 1 % residual fat in a second extraction step. The theory is that flaking the hexane-moist material bursts the oil cells. This process has been applied only on a small scale (ca. 5 t/h).

Figure 10. Kennedy extractor

A more recent development is the Alcon process [39] for soybeans, in which the essential step is to heat the flakes to ca. 100 °C with direct steam, followed by drying. The special flake conditioning prior to extraction deactivates enzymes such as phospholipases and lipoxygenase, and presumably dissociates lipoprotein complexes; this leads to lower residual fat contents in the meal and a more easily deslimable crude oil with improved oxidation characteristics.

Extracted oilseeds can be desolvized in a series of horizontal steam-jacketed tubes. The material is propelled through the tubes by screws and is then passed through toasters, similar to stack cookers, that are heated by both live and indirect steam. Alternatively, desolventization can be performed in one step in desolventizers – toasters. After drying and cooling, the meal is ready for use as an animal feed component. Toasting not only reduces residual solvent to levels below the lower explosion limit but also deactivates nutritionally undesirable enzymes such as urease and trypsin. In some cases, superheated solvent vapor is used for desolventization. This process and flash desolventization are used when minimal protein denaturation is desirable.

Solvent is recovered from the filtered miscella by distillation in multiple-stage evaporators, which are constructed to minimize thermal damage to the oil. The miscella is first concentrated to 96 % oil and finally stripped with injected steam in a falling-film evaporator. The vapors from the toaster, dryer, cooler, and dis-

tillation unit are condensed and separated into water and hexane, which is recycled. Vented air is passed through special adsorbents such as activated charcoal or mineral oil to recover solvent. Total solvent loss is 0.2 – 0.3 %, based on seed input.

5.2. Land-Animal Fats

Animal fats can be readily isolated from tissue by heating since the cell membranes of animal cells are much weaker than those of plant cells. The intracellular fat expands on heating and bursts the membrane. Extraction with solvents is limited to offal. Fatty tissue is particularly susceptible to decomposition so that rapid processing is necessary if refrigeration is not possible. Microbial and autolytic degradation rapidly lead to oxidation, hydrolysis, color deterioration, and unpleasant odors and flavors, which are difficult to remove from the fat. The free fatty acid content therefore serves as a convenient, primary quality criterion.

In *dry rendering*, the comminuted fatty tissue is digested by cooking in steam-jacketed vessels equipped with agitators [40]. Local overheating of fatty tissue must be avoided since this can easily lead to unpleasant off-flavors. In modern automated plants for working up animal byproducts, the raw material is first heated and sterilized in a dry-rendering vessel. The resulting sludge is then separated, possibly after predrying, into crude meal (cracklings) and a liquid phase containing fat and water by a continuous screw press (see Fig. 11, Krupp Kontipress process) or by a decanter, i.e., a centrifuge with a built-in screw conveyor (Alfa–Laval Centrimeal process). The fat is finally separated from the aqueous phase by centrifuging. The 7 – 12 % residual fat con-

tent of the meal can be reduced to 1 – 4 % by solvent extraction.

Wet rendering, which involves treating the fatty tissue with direct steam, tends to give better yields and quality than dry rendering. In modern continuous rendering plants (e.g., as built by Alfa – Laval, Westfalia, and Sharples) selected tissue is coarsely comminuted and heated to 50 – 60 °C. It is then heated quickly to 80 – 90 °C with direct steam to deactivate oxidizing enzymes. The greaves are then separated in a decanter centrifuge, and the fat is clarified by further centrifuging, cooled, possibly texturized, and packed (Fig. 12). Fat obtained by this method in up to 99 % yield contains 0.1 – 0.2 % moisture; the content of free fatty acids is virtually identical with that of the raw material. This mild processing technique minimizes the formation of off-flavors. Further refining of lard or tallow for edible purposes is controlled by national legislation.

5.3. Marine Oils

Whale oil is isolated by rendering. The blubber is cooked with live and indirect steam, and the oil is then separated by centrifugation from insoluble tissue and water-soluble matter.

Similar processes are used to isolate *fish oils* [41]. Crushed fish (herring, menhaden, sardines, pilchards) with a dry matter content of 15 – 22 % is first cooked in closed vessels at relatively low pressure. This operation sterilizes the fish and coagulates the protein to produce a fish mass that can be easily pressed. Subsequent screw pressing separates most of the water and oil from the press cake. The press water is prepurified over screens or with a decanter (desludger) and then separated by centrifugation into crude fish oil and stickwater (or glue water). The press cake (ca. 50 % water) is dried, sometimes also extracted with a solvent, and ground into fish meal. Evaporation of the stickwater gives solubles which are added to the meal. Industrial plants are offered by Alfa – Laval (Centrifish) and Westfalia (see Fig. 13)

Liver oils are usually obtained on board ship by mild rendering of crushed liver, sometimes assisted by pressure-release disintegration of the oil cells, and subsequent separation in centrifuges. The Solexol process used in South Africa employs liquefied propane as the extraction solvent. This method can also be used to fractionate fishliver oils and to isolate vitamin concentrates.

5.4. Synthetic Fats

Pure synthetic glycerides [20] and phospholipids have few industrial uses. Synthetic fats for edible purposes are of little importance with the exception of specific dietary products such as medium-chain triglycerides of C_8 and C_{10} fatty acids (MCT fats), which are administered in some postsurgical cases [42].

6. Refining

Crude oils and fats obtained by expelling, extraction, or rendering contain trace components which are undesirable for taste, stability, appearance, or further processing. These substances include seed particles, dirt, phosphatides, carbohydrates, proteins, fatty acids, trace metals, pigments, waxes, oxidation products of fatty acids, and toxic components such as polycyclic aromatic hydrocarbons, gossypol, mycotoxins, sulfur compounds (in fish and cruciferous oils), and pesticide residues. The aim of refining edible fats and fats for industrial purposes is to remove these undesirable components as far as possible without significantly affecting the concentration of desirable constituents such as vitamins and polyunsaturated fatty acids, and without significant loss of the major glyceride components. Some oils, such as olive oil, butterfat, and cold-pressed sunflower oil or linseed oil, are not refined in order to preserve their typical flavors.

Refining usually involves the following stages:

1) Precleaning to remove phosphatides (degumming)
2) Neutralization by treatment with lye or by distillation
3) Decolorization by adsorptive treatments (bleaching)
4) Deodorization or stripping in vacuo

6.1. Degumming [43]

Phosphatides, gums, and other complex colloidal compounds can promote hydrolysis of an oil or fat during storage and also interfere with subsequent refining. They are therefore removed by degumming or desliming.

The degumming method depends on the type of the oil and the phosphatide content. In hydration degumming, which involves treating the oil or fat with water or steam, phosphatides absorb water to form a sludge that is insoluble in the oil. This process is used to remove soy lecithin (1 – 3 %) from soybean oil: 2 – 5 % water, based on oil, is intimately mixed with the crude oil at 70 – 80 °C; after a contact time of 1 – 30 min the phosphatide sludge is separated by centrifuging. The degree of hydration can be increased by using acids such as citric or phosphoric, bases, or salts but at the expense of lecithin quality. Such modified hydration processes are therefore confined to post-degumming and to oils whose lecithins have little commercial value. Degumming and neutralization can also be carried out together but usually with increased losses of neutral oil owing to the formation of emulsions. The use of sulfuric acid is generally restricted to industrial oils that are not to be further refined.

Some technical oils such as linseed oil can be degummed by heating to 240 – 280 °C; the precipitation of gums on heating is referred to as oil "breaking."

Precleaning of a crude oil by treatment with bleaching earth or other adsorbents, normally in combination with acids such as phosphoric or citric, can be advantageous.

Oils that are refined by distillation (physical refining, see page 32) should have a very low phosphatide content. This can be achieved by special degumming techniques involving the addition of citric acid followed by hydration at ca. 20 °C for several hours before centrifugal separation [44]. Another "superdegumming" technique involves separating the phosphatide micelles from a solution of the crude oil in hexane by ultrafiltration using special polysulfone or polyacrylonitrile membranes [45].

6.2. Deacidification (Neutralization)

Commercially available crude oils and fats contain on average 1 – 3 % free fatty acids. Whereas a soybean oil can have as little as 0.5 % free fatty acids, some palm and fish oils can contain up to 10 %. The free fatty acid content of refined fats should be below 0.1 %. Although longer

chain fatty acids do not generally affect taste, the short-chain acids can impart a soapy, rancid flavor. When the free fatty acids are removed as soaps by treatment with lye, other undesirable constituents such as oxidation products of fatty acids, residual phosphatides and gums, phenols (e.g., gossypol), and aflatoxins are also "washed out." In practice, deacidification is performed mainly by treatment with lye or by distillation. Deacidification by esterification with glycerol, by selective extraction with solvents, or by adsorbents is not industrially important.

Alkali Neutralization [46]. The usual method of alkali neutralization is treatment with weak lye, either batchwise or continuously. The more concentrated the lye, the more readily are undesirable constituents taken up in the soapstock. Dilute alkaline solutions (ca. 1 N) do not saponify the oil, but greater neutral oil losses occur due to occlusion in the soapstock. The losses increase with increasing content of free fatty acids. Concentrated lye (4 – 7 N) yields a relatively concentrated soap which takes up little neutral oil, but it can saponify substantial amounts of the neutral oil, especially in those oils that have a relatively high proportion of short-chain fatty acids. The optimum lye concentration therefore depends on the quality of the crude oil and the desired quality of the refined product. The neutralization process can be further influenced by temperature, residence time, and mode and intensity of mixing the lye and the fat phase.

Batch neutralization is done in an open or closed vessel (up to 75 t content) with a conical base. The reactor is fitted with a heating mantle, heating coils, and facilities for injecting live steam (Fig. 14). Lye and oil can be mixed without undue emulsification by using special coil and frame stirrers. Soap settles in the conical bottom of the neutralization vessel. Discharge of neutral oil with the soap can be minimized by using ultrasonic or dielectric measurement of the phases. Closed vessels can also be used for bleaching if they can be evacuated. Whereas weak lye is generally sprayed onto the oil at ca. 90 °C without stirring, stronger lye is normally stirred into the oil at 40 – 80 °C. Sodium carbonate is sometimes used instead of caustic soda; it does not saponify but tends to lead to foaming. Oils with a relatively high concentration of free fatty acids are neutralized with strong lye in order to limit the total volume. The required amount of lye, including a slight excess, is based on the free fatty acid content (ffa).

Figure 14. Combined neutralizer – bleacher

After neutralization and discharge of soapstock, the oil is washed with dilute lye (ca. 0.5 N) and then with water in order to reduce the soap content below 500 ppm. Incomplete removal of soap impairs the color of the oil and the efficacy of the following refining steps. Polyunsaturated oils such as soybean oil are sometimes subjected to posttreatment with sodium carbonate – silicate to remove residual traces of oxidized glycerides and phosphatides. Although soapstock can be utilized as such in chicken broiler feed, it is normally converted into "acid oil" (a mixture of fatty acids and neutral oil) by batch or continuous treatment with 30 % sulfuric acid at 70 °C.

The quantity of acid oils is a measure of the refining efficacy. A refining factor of 2 means that for each mass unit of free fatty acid in the crude oil, 2 mass units of acid oil are produced. The difference between acid oil and free fatty acid content is mainly due to occluded neutral oil. Acid oils are used for technical purposes and as energy carriers in animal feeds [47].

Batch neutralization is more flexible than continuous neutralization but gives lower refining yields.

Continuous processes achieve the same or greater capacities in a smaller space with better yields, provided long continuous runs can

Figure 15. Flow diagram of continuous neutralization of oils and fats
a) Crude oil storage tank; b) Gum conditioning mixer; c) Neutralizing mixer; d) Separator (centrifuge); e) Re-refining mixer; f) Water-washing mixer; g) Vacuum dryer

be maintained. Continuous plants from Alfa–Laval, Westfalia, and Sharples are widely used (Fig. 15). In these plants, the oil is generally first conditioned by addition of citric or phosphoric acid in small continuous mixing chambers and then brought into contact with lye. Soap and gums are separated in centrifuges. After re-refining and passage through a washing centrifuge, the oil is practically free of fatty acid and soap. The Sharples plant uses high-speed open centrifuges with a high separation efficiency, while the Alfa–Laval short-mix lines employ completely closed centrifuges with a mean residence time of only a few seconds. The capacity can be increased considerably by using self-discharging centrifuges (e.g., from Westfalia).

The Zenith process employs a different principle: a fine stream of oil rises through a vessel filled with dilute caustic soda and is skimmed off continuously at the top. The spent lye must be replaced. This type of neutralization requires efficient pre-degumming and has the advantage of relatively low losses of neutral oil [48].

Neutralization with aqueous ammonia is an old process which is being reexamined because of environmental pollution problems with lye. The ammonium soaps can be separated by centrifuging and split into fatty acids and ammonia by heating, the ammonia being recycled [49].

Distillative Neutralization. In distillative neutralization (physical refining) the free fatty acids are continuously removed from the crude oil with water vapor in vacuo. Prior to this stripping, gums, phosphatides, and trace metals must be almost completely removed since these compounds impair the oil quality during distillation. They are preferably removed by treatment with acids and bleaching earth.

The economics of distillative neutralization improve with increasing content of free fatty acids. The fatty acid factor is approximately 1.1, thus the neutral oil losses are far lower than with alkali neutralization. An added advantage is the avoidance of soap-stock splitting and the consequent effluent problems. Distillative neutralization was formerly restricted to fairly saturated oils with a high free fatty acid content (e.g., coconut oil, palm oil, and tallow). However, it is now being extended to polyunsaturated oils such as rapeseed, soybean, and sunflower oil because techniques are available for reducing the phosphatide content of the crude oils to sufficiently low levels to obviate lye neutralization [50].

Temperatures between 240 and 270 °C are normally used to achieve free fatty acid contents of less than 0.1 %. At these temperatures decomposition and removal of carotenoid pigments result in a significant bleaching effect, this is particularly noticeable in palm oil. Older plants such as those built by Wecker and Feld & Hahn have now been generally superseded by modern plants (e.g., Lurgi, Girdler, HLS, and EMI), which have the advantage of a smaller spread in residence time and hence better process control (especially in combined deacidification, deodorization, and heat bleaching). The latter plants are very similar to the corresponding

deodorizer plants (see Figs. 20 and 21) except for an additional fatty acid condenser between the deodorizer and the vacuum assembly.

Other Processes. *Esterification* of the free fatty acids with glycerol may be economically feasible for highly acid oils. The esterification is carried out at 160 – 210 °C in the presence of catalysts such as magnesium oxide, alkali silicates, or metals (Zn or Sn).

Solvent extraction of free fatty acids is of interest only for highly acid oils. Olive oil with 22 % ffa can be deacidified to ca. 3 % ffa by liquid – liquid extraction with ethanol. Furfural can be used to dissolve polyunsaturated glycerides and fatty acids.

In the Solexol process, liquefied propane is used as solvent. Saturated glycerides are taken up in the propane phase while nonsaponifiable matter, fatty acids, oxidation products, and polyunsaturated glycerides remain largely undissolved. This process has been used to fractionate fish and fishliver oils and may increase in importance with the advent of supercritical fractionation and extraction techniques.

Various adsorbents such as silica gel and alumina have been proposed for the *selective adsorption* of free fatty acids [51]. Adsorption on strongly basic ion-exchange resins has also been used. Plant-scale application of such processes has, however, not been reported.

6.3. Bleaching

Degumming followed by alkali neutralization generally does not lead to significant decolorization of an oil or fat. A bleaching step with solid adsorbents such as bleaching earth or activated charcoal is normally employed. Bleaching with air or chemicals is not used for edible fats.

The aim of adsorptive treatment is to remove pigments such as carotenoids and chlorophyll but also residues of phosphatides, soaps, trace metals, and oxidation products such as hydroperoxides and their nonvolatile, polar decomposition products. These compounds can have a deleterious effect on the course of further processing (especially hardening and deodorization) and on the quality of the final product. Some of the oxidation products that are removed by adsorption can promote oxidation of the oil. Since some of these undesirable compounds can be removed by suitable degumming and neutralization, there is an interdependence between the pretreatment conditions and the treatment with adsorbents. This interdependence can also involve deodorization (heat bleaching) where, for example, the carotenoid content is reduced.

The adsorption of pigments follows Freundlich's isotherm: the amount of pigment adsorbed decreases with decreasing concentration of the pigment in the oil. Although adsorption should be most efficient if the oil is passed through a layer of adsorbent, in practice the adsorbent is normally stirred into the oil and then filtered off after a certain residence time.

The choice of the adsorption process and the type and concentration of adsorbent is governed by factors such as pretreatment, desired quality of the fully refined product, filtration speed of the oil, and oil retention by the adsorbent. Oil retention can be up to 50 wt % on bleaching earths and nearly 100 wt % on activated charcoal.

Natural and activated earths are the most frequently used adsorbents in the refining of oils and fats. Activated earths are obtained by leaching natural earths (predominantly aluminum silicates containing montmorillonite) with hydrochloric acid followed by washing with water, drying, and sizing. This process increases the internal surface of the bleaching earth by partial dissolution of the aluminum and iron oxides; calcium and magnesium ions are partially replaced by hydrogen ions.

The amount of bleaching earth to be used and the optimum bleaching conditions must be determined empirically. Lower concentrations (0.5 – 1.0 %) are required for activated earths than for natural earths. Activated earths catalyze oxidation of the oil. For this reason bleaching should be done below 100 °C in vacuo, and the subsequent filtration should be carried out with limited access of atmospheric oxygen. Bleaching is sometimes performed in two steps: a conditioning and adsorption stage at relatively low temperature (ca. 65 °C), and a second stage at elevated temperature (ca. 100 °C) to fix the adsorbed components onto the adsorbent surface [52].

In physical refining, bleaching is often preceded by addition of citric or phosphoric acid to chelate trace metals and to precipitate hydrated

phosphatides. This can also be achieved by using bleaching earths containing added acid.

The moisture content of bleaching earths lies between 5 and 10 %. Except for some types of natural earths, the moisture content does not appear to have a significant influence on bleaching capacity.

Activated charcoal (0.1 – 0.4 %) is sometimes used in combination with bleaching earth for oils that are difficult to bleach. Activated charcoal has also assumed importance as an adsorbent for removing polycyclic aromatic hydrocarbons from oils and fats [53]. It has been recommended for use in a fixed-bed process for the physical refining of soybean oil [54].

Bleaching and filtration is still mostly done *batchwise*. The oil is first dried in vacuo at ca. 30 kPa (30 mbar) to an optimum moisture content, frequently in the same closed vessels in which the oil was neutralized and washed (Fig. 14). The required amount of adsorbent is then drawn into the oil at 80 – 90 °C, preferably through a pipe reaching into the oil. After stirring for a few minutes to half an hour in vacuo, the oil – earth slurry is pumped over filter presses. Automated frame and plate presses or centrifugally dischargeable, closed-disk filters of the Funda (Fig. 16) and Schenk type are preferred; these also have the advantage of limiting access of air. The filter cake, containing 30 – 50 % oil, is often extracted with hot water (Thomson process) or with hexane to recover the bulk of the adsorbed oil. The quality of the recovered oil depends on the degree of unsaturation, the type of extraction, and the age of the spent earth before extraction. It is normally not economic to regenerate spent bleaching earth.

Figure 16. Closed disk filter with centrifugal discharge (Funda)

Continuous bleaching is especially relevant when the other refining steps are also performed continuously. The degummed or degummed and neutralized oil is normally dried and deaerated in vacuo and charged together with bleaching earth into an evacuated vessel where the oil – earth slurry is fed through various compartments, possibly at different temperatures, and is then filtered in a closed-disk system (Fig. 17).

Figure 17. Alfa – Laval bleach system
a) Plate heat exchanger; b) Bleacher; c) Filters; d) Polishing filters; e) Bleaching-earth dosage equipment; f) Bleaching-earth storage tank, g) Cyclone

Bleaching with oxygen or chemicals is not practiced for edible fats and is used only occasionally for technical fats. Oxidizing agents such as hydrogen peroxide, sodium peroxide, benzoyl peroxide, potassium permanganate, chromium salts, hypochlorite, and chlorine dioxide, and reducing agents such as sulfurous acid and sodium dithionite have been proposed. Hydrogen peroxide is used when adsorptive methods do not suffice. Castor, coconut, peanut, and olive oils and certain types of tallow and bone greases can be successfully bleached with 0.05 – 0.1 % of a 20 % aqueous solution of sodium chlorite. Fats such as red palm oil are sometimes bleached by very slight hydrogenation which destroys carotenoid pigments.

6.4. Deodorization

Deodorization is the last step of the refining sequence, in which odors and flavors are removed from the bleached oil or fat. It is essentially a steam distillation process in which volatile compounds are separated from the nonvolatile glycerides. The odoriferous compounds are primarily aldehydes and ketones formed by autoxida-

tion during handling and storage and can have a flavor threshold value of a few ppm. Other volatile components such as free fatty acids, alcohols, sterols, or tocopherols are also partially removed by deodorization.

Deodorization is not, however, a purely physical process. During deodorization, flavor compounds can be formed by hydrolysis and thermal decomposition, and peroxides are decomposed by heat. These reactions presumably play a major role in the flavor stability improvement achieved by deodorization, especially in vegetable oils. In practice, therefore, the residence times and steam volumes required are significantly greater than those calculated for normal steam distillation. At the relatively high deodorization temperatures used, traces of air can initiate oxidation with severe impairment of taste and flavor stability. Because thermal decomposition products of proteins, carbohydrates, phosphatides, and soaps can also interfere with deodorization, the oil must be well prerefined, i.e., freed from phosphatides and soap.

Deodorization is performed in vacuo because of the low partial vapor pressure of the compounds to be removed. Consumption of stripping steam increases with decreasing vapor pressure of the volatile components and with increasing pressure in the deodorizer, it ranges from 5 to 10 wt % (based on the oil) for batch processes and from 1 to 5 wt % for continuous processes. Deodorization temperatures range from 190 to 270 °C and the pressure from 0.13 to 0.78 kPa (1 – 6 mm Hg). The volume of stripping steam required is 10 – 20 m^3 per kilogram of oil [24]. Carry-over losses of oil are minimized by limiting the velocity of the injected steam, by providing a sufficiently large headspace, and by baffles. The distillate removed during deodorization is about 0.2 % of the oil, and contains very little neutral oil. In a batch process a deodorizing time of at least 2 h is required for saturated or hydrogenated fats; about 4 h is needed for other oils and fats. Although attempts have been made to determine the end point of deodorization by analytical data, in practice this is done organoleptically.

The steam injected into the oil must be dry and oxygen-free. In order to deactivate prooxidative trace metals, aqueous citric acid solution (2 – 5 mg of citric acid per 100 g of oil) is often injected into the oil toward the end of the deodorization.

The deodorizer is normally constructed of stainless steel if temperatures of 190 °C are to be exceeded. Deodorizing temperatures up to 270 °C are employed, for example, to complete removal of pesticide residues [55], to heat-bleach palm oil, and to complete removal of free acids during physical refining. Since dimerization and isomerization of fatty acid groups increase with time and temperature [56], a deodorization at 270 °C should not last more than 30 min.

Batch deodorizers are still widely used (Fig. 18). They are about twice as high as they are wide and are normally half-filled to provide sufficient head space. Their capacity can vary from 5 to 25 t. The bottom part is fitted with heating coils and a steam distributor through which stripping steam is injected into the oil. The vacuum system (0.6 – 1.2 kPa) comprises a booster and ejector assembly. Barometric condensers can be eliminated by using dry condensing plants. When deodorization is completed, the oil is cooled to ca. 90 °C in the deodorizer and to 40 – 60 °C in a subsequent vacuum cooler; cooling minimizes oxidation that occurs on contact with atmospheric oxygen at elevated temperatures. The total cycle of charging, heating, deodorization, cooling, and discharging requires up to 8 h, the deodorization process itself up to 4 h. The deodorizer distillate has the appearance of a milky emulsion and contains calcium soaps, nonsaponifiable matter, and a small fraction of neutral oil.

Figure 18. Batch deodorizer
a) Barometric condenser; b) Fat trap; c) Heating steam; d) Stripping steam; e) Steam distributor

Semicontinuous and continuous deodorization systems are replacing batch deodorizers because of the savings in steam resulting from more efficient stripping and heat recovery.

The semicontinuous Girdler deodorizer (Fig. 19) consists of an iron shell fitted with stainless steel trays. At defined time intervals (e.g., every 30 min), a certain quantity of oil flows into the top tray of the deodorizer where it is deaerated in vacuo and then heated to ca. 170 °C by exchange with the hot effluent oil. After 30 min the oil is discharged into the second tray where it is heated to the operating temperature (normally 230 – 250 °C). Injection of steam (at 0.6 – 1 kPa) takes place in the 3rd and 4th trays, and cooling in the 5th tray. Operation of the unit is made fully automatic by use of a timing device which opens and closes the oil valves. The semicontinuous Lurgi plant works on a similar principle (Fig. 20); the stripping steam is injected through special orifices and further distributed through the oil by steam-lift pumps. These types of deodorizers have capacities of up to 20 t/h.

Figure 19. Semicontinuous deodorizer (Girdler)
a) Heating steam; b) Vacuum aggregate; c) Cooling water; d) Stripping steam

Fully continuous deodorizers generally comprise a high cylindrical column fitted with a number of trays with bubble caps or similar devices, down which the oil flows countercurrent to the stripping steam. The oldest continuous deodorizer is probably that built by Foster – Wheeler. Modern versions [57] are made by EMI, Gianazza, Mazzoni, Wurster & Sanger, Votator, de Smet, Ex-Technik, HLS, Lurgi, and Krupp (Fig. 21). An alternative construction is that of EBE in which the oil flows countercurrent to the stripping steam in horizontal tubes. The Campro deodorizer has a continuous tray-in-shell design that combines plug flow with a unique thin-film stripping concept.

7. Fractionation

The aim of fractionating fats is to remove either undesirable components or to isolate desired components with special properties. Edible oils can, for example, be winterized by removing waxes and saturated components; cocoa butter substitutes can be obtained from palm oil. Except for the molecular distillation of monoglycerides, distillative techniques cannot be employed. Industrial fractionation techniques are based on crystallization or liquid – liquid extraction. Separation of glycerides by selective adsorption is only used occasionally for purification purposes. Fractional crystallization can be subdivided into dry processes, processes employing solvents, and processes involving selective wetting of fat crystals. Directed interesterification combines selective fractionation with interesterification (see Section 4.2).

The oldest example of *dry fractionation* is the separation of tallow into stearin and olein by pressing; this separation came into use toward the end of the 19th century in connection with the production of margarine. The lower-melting glycerides (olein) were squeezed out of the crystal network of the higher-melting glycerides by pressing blocks of tallow wrapped in filter cloth.

Figure 20. Flow diagram of a semicontinuous deodorization plant (Lurgi)

This method has been superseded by modern processes (Fig. 22) in which the fat is slowly chilled to the required temperature under controlled conditions in tempering vessels fitted with low-speed agitators, or in scraped coolers. Relatively large crystals of the higher-melting glycerides are obtained which can readily be filtered off in filter presses or drum filters. Slow cooling is important to obtain a relatively small number of nuclei which can then grow into large crystals. In addition, slow cooling promotes selective crystallization of the higher-melting glycerides and avoids the formation of mixed crystals containing both high- and low-melting glycerides. The difference in melting point must be at least 10 °C to achieve a sufficiently sharp, reproducible separation.

Figure 22. Dry fractionation plant
a) Crystallizers; b) Circulating unit; c) Feed pump; d) Recycling pump; e) Florentine filter

Winterization of edible oils such as sunflower or cottonseed oil involves removing waxes, which cause turbidity at refrigerator temperatures. After bleaching or deodorization, the oils are kept at ca. 10 °C for at least 1 h and then filtered. An alternative process is to combine dewaxing with superdegumming of the crude oil

(see also Section 6.1) [44]. Peanut oil is not normally winterized because its turbidity is caused by small glyceride crystals that are difficult to filter.

The separation of higher- and lower-melting glycerides can be improved by *fractionation using solvents* such as hexane, acetone, or methanol, in which the unsaturated fats are more readily soluble. Costs are much higher than for dry fractionation because of the need for solvent recovery. This relatively sharp fractionation method is generally only economical for preparing specialty products. For example, fractionation of palm oil with acetone gives a fraction (ca. 40 % of the feed) consisting of disaturated-monounsaturated glycerides, primarily 1,3-dipalmito-2-olein.

The separation of relatively small fat crystals can be facilitated by *selective wetting*, for example with sodium lauryl sulfate or decyl sulfate in aqueous solution. The crystal suspension, produced either batchwise or continuously, is mixed with an aqueous solution containing the wetting agent and normally also an electrolyte such as magnesium sulfate. The crystals covered with wetting agent migrate to the aqueous phase as a suspension that can be separated by centrifugation. Alfa – Laval recommends such a process (Lipofrac process) for the fractionation of palm oil and for the winterization of other oils.

Selective extraction [58] has long been used in refining mineral oil. Liquefied hydrocarbons or furfural are used as selective solvents in the separation of fats and fatty acids. This technique not only permits the separation of fats and fatty acids according to the degree of unsaturation or the molecular mass, but also effects the partial removal of coloring matter, gums, and vitamins.

Liquefied propane preferentially dissolves saturated components (Solexol process; see also page 33) [59]. This process has been used to fractionate tallow. The solubility of fats and fatty acids increases with decreasing molecular mass. Furfural preferentially dissolves unsaturated components. It is miscible with fatty acids and monoglycerides at room temperature, but with triglycerides only at elevated temperatures. Depending on the operating temperature, furfural is used alone or together with hexane. The selective solubility behavior is less pronounced for differences in molecular mass [60]. The furfural process has been used to produce high-performance drying oils from soybean and linseed oils.

8. Hydrogenation [61], [62]

Hydrogenation of the carbon – carbon double bonds of unsaturated glycerides leads to an increase in melting point (hardening, see also Section 4.3). The combination of hydrogenation, interesterification, and fractionation offers the opportunity of economically meeting the increasing demand for specialty products for foodstuff and technical applications from available raw materials.

Trans fatty acids produced by isomerization during hydrogenation also occur in animal fats such as butterfat and tallow. Although there are indications that trans fatty acids may be metabolized differently from their cis isomers [63], long-term studies have demonstrated their toxicological safety [64]. As far as their effect on blood lipid levels is concerned, they are comparable with saturated fatty acids.

The selectivity of hydrogenation is determined by the type and activity of the catalyst [65] (controlled poisoning and a large pore size increase selectivity), the operating temperature (both selectivity and cis – trans isomerization increase with increasing temperature), stirring – mixing efficacy (increasing the hydrogen concentration at the catalyst surface by intensive stirring – mixing reduces selectivity), and the hydrogen pressure (increasing the pressure reduces the selectivity).

Neither absolute selectivity nor complete isomerization (or complete suppression of isomerization) can be achieved. However, the process can be steered in a desired direction by suitable choice of the above parameters to produce fats with different degrees of saturation and melting properties from a given oil. For example, peanut oil can be hardened nonselectively to an iodine value of 70 – 90 yielding a soft, semiliquid fat. If the same oil is hardened to the same iodine value under conditions that promote isomerization, a firm, plastic fat with a melting point of ca. 33 °C is obtained. Palm oil is sometimes hydro-bleached, i.e., hydrogenated under very mild conditions that lead to selective hydrogenation of carotenoids.

The oil should be at least degummed and bleached prior to hydrogenation and preferably neutralized and bleached as well. Catalyst poisons include phosphatides, sulfur compounds, soaps, and oxidation products from poor handling and/or bleaching. Free fatty acids do not poison the catalyst but tend to slow down the hydrogenation reaction.

The hydrogen must be pure and dry and can be produced by various routes. The most important industrial process is decomposition of natural gas or propane by passage over a nickel catalyst in the presence of steam at 800 – 900 °C. Electrolysis of water is used to a lesser extent. The hydrogen must be specially purified to remove hydrogen sulfide and carbon monoxide, which are strong catalyst poisons.

Figure 23. Flow diagram of a batch hardening plant
a) Converter; b) Filter press; c) Catalyst tank; d) Catalyst pump

Nickel, platinum, and palladium are preferred catalysts. Platinum and palladium are especially suited for laboratory-scale and low-temperature hydrogenations. Only nickel is used on a production scale. Many different types of nickel catalysts are available (→ Heterogeneous Catalysis and Solid Catalysts). They essentially consist of metallic nickel on a carrier such as silica gel, silicic acid, or alumina. The carrier is treated with a nickel salt such as the carbonate, hydroxide, or sulfate, which is converted into nickel oxide by roasting. The oxide is then reduced to metallic nickel in a stream of hydrogen at 300 – 400 °C. Other routes involve decomposition of nickel formate at 240 °C or dissolution of aluminum from a nickel – aluminum alloy with alkali (Raney catalyst). In addition, there are a number of mixed catalyst systems (copper, chromium, cobalt) with special selectivities.

Batch hydrogenation (Fig. 23) is normally performed on a scale of 5 – 25 t. The dry oil is pumped into the hydrogenation vessel that has been previously flushed with hydrogen, and heated to just below the required operating temperature (100 – 180 °C). The catalyst (0.01 – 0.1 % active nickel) is then introduced and the hydrogen pressure increased. Alternatively, the oil is vacuum-deaerated while it is heated before the catalyst and hydrogen are introduced. Hydrogenation is an exothermic reaction; a decrease in the iodine value of one unit causes a temperature increase of 1.5 – 2.0 °C. The required operating temperature is therefore maintained by controlled cooling. Hydrogen is introduced through a sparge ring at the bottom of the hydrogenation vessel, pumped out at the top, and recirculated. Sparging and fast stirring ensure adequate dispersion of the catalyst in the oil and optimum mass transport. The usual working pressure is 0.15 – 0.3 MPa (1.5 – 3 bar).

Figure 24. Hydrogenation converter (dead-end design)
a) Heating and cooling coil; b) Turbine agitator; c) Baffle

In hydrogenation autoclaves that operate without hydrogen recirculation ("dead-end" process), spent hydrogen is replaced at a somewhat higher pressure [66]. The intensive stirring required can be achieved with a turbine agitator or similar device (Fig. 24).

So-called loop hydrogenation reactors (e.g., Buss, Fig. 25) have become increasingly popular. The oil – catalyst mixture is constantly circulated through an external heat exchanger during heating and cooling. This loop reduces total cycle time; it also gives better temperature control and thus less product variation from batch to batch.

Figure 25. Loop hydrogenation reactor
a) Autoclave; b) Mixing and reaction zone; c) Reactant – solvent – catalyst suspension; d) Primary loop recirculation pump; e) Primary loop heat exchanger

When hydrogenation is complete, the product is cooled to 80 – 90 °C and the catalyst is filtered off. Since the acid value tends to increase slightly during hydrogenation, the crude hardened fat is usually postneutralized with lye and bleached before it is deodorized. Posttreatment with citric or phosphoric acid, followed by bleaching prior to deodorization, is an alternative to lye posttreatment. In either case the residual nickel content is reduced to <0.2 ppm. Deodorization of a hardened fat is essential since hydrogenation leads to typical hardening flavors which must be removed.

Continuous hydrogenation is primarily suitable for the production of one particular product over a longer period of time. Fully continuous processes are the exception rather than the rule. In semicontinuous processes several reaction vessels or autoclaves are arranged sequentially (e.g., Alfa – Laval system). In fully continuous plants, either the preheated oil and hydrogen are passed over a stationary catalyst bed, or all three components are mixed prior to entering the reactor (see Fig. 26). In the Procter & Gamble process, the reactor contains a special stirrer to ensure intensive mixing in a thin film. The Girdler Corporation developed a process in which three Votator heat exchangers are arranged sequentially; the first vessel serves as preheater, the second as a hydrogenator, and the third as a cooler. Continuous hydrogenation of miscella at low temperatures over a catalyst bed produces little isomerization but has not achieved industrial importance.

Figure 26. Continuous hydrogenation of fatty acids and fatty oils (Lurgi)
a) Dryer; b) Reactor

The course of hydrogenation is normally monitored by changes in analytical data such as iodine value or refractive index. The hydrogenated products are characterized primarily by melting point and solids content at different temperatures.

9. Interesterification

Prior to interesterification, fats must be neutralized to less than 0.1 % ffa and dried to avoid excessive deactivation of the catalyst, which is normally sodium ethoxide (see also Section 4.2). The catalyst (0.1 – 0.3 %) is finely dispersed in the fat. After completion of the interesterification reaction, which is carried out at 80 – 100 °C, excess catalyst is deactivated by addition of water. The resulting soap is removed by washing with water and bleaching. During interesterification, sodium ethoxide is converted into fatty acid ethyl esters, which are removed during the final deodorization step.

Interesterification can be performed batchwise (Fig. 27), usually in a neutralization–bleaching vessel, or continuously. In the continuous process, fat with suspended catalyst passes through a tubular reactor (Fig. 28) [67]. In directed interesterification (see Section 4.2) the fat is cooled, for example, in a scraped-surface cooler to crystallize the higher-melting glycerides.

Figure 27. Batch reactor for interesterification

Figure 28. Continuous interesterification
a) Heat exchanger; b) Dryer; c) Homogenizer; d) Tubular reactor; e) Mixer; f) Centrifuge; g) Dryer

New types of fats can be created by suitable choice of interesterification components. Depending on the starting components, the melting point of the fat after interesterification can be lower or higher. Figure 29 shows the solids content (dilatation) curves of native and interesterified palm oil; the glyceride composition is given in Table 22.

Acidolysis. An example of the industrial application of acidolysis is the transesterification of coconut oil with acetic acid and the subsequent esterification of excess acid with glycerol. A mixture of aceto fats (laurodiacetin, myristodiacetin, etc.) is obtained which are used as plasticizers and coatings. Transesterification of coconut oil with higher fatty acids, employing continuous distillation of the liberated lower fatty acids ($C_6 - C_{10}$), yields fats with properties similar to those of cocoa butter. Acidolysis is usually performed in the presence of an acid or base catalyst; no catalyst is required at temperatures of 260 – 300 °C.

Figure 29. Solids content of native and interesterified palm oil (Alfa – Laval)
a) Native palm oil; b) Randomly interesterified palm oil; c) Directedly interesterified palm oil

Alcoholysis. The replacement of the glycerol moiety of a fat with lower monohydric alcohols proceeds at lower temperatures. The Bradshaw process [68] utilizes transesterification of fats with methanol as the first step in the continuous production of soap. Fat with an acid value of less than 1.5 is stirred with excess methanol for a few minutes in the presence of 0.1 – 0.5 % caustic soda at ca. 80 °C. On subsequent standing, practically dry glycerol settles at the bottom of the reaction vessel. The same principle is em-

Table 22. Fatty acid and glyceride composition of native and interesterified palm oil *

U_3	6	12	24

* S = saturated fatty acid. U = unsaturated fatty acid.

ployed in the preparation of fatty acid methyl esters for laboratory analyses. If the acid value is higher than 1.5, boron trifluoride is normally used as a catalyst.

The exchange of glycerol with other polyhydric alcohols, such as pentaerythritol, is best done under conditions at which glycerol can be distilled off, i.e., at 200 – 250 °C and 5 – 40 kPa (50 – 400 mbar), in the presence of an alkaline catalyst.

The production of mono- and diglycerides by reacting fats with an excess of glycerol is a special case of transesterification of fatty acid esters with polyhydric alcohols. These glycerides are especially important as emulsifiers. The production process consists of heating a fat with 25 – 40 % glycerol at 205 – 245 °C in the presence of sodium hydroxide or a sodium alkoxide. Part of the catalytic effect is probably based on soap enhancing the solubility of glycerol in fat. Industrial products contain 40 – 50 % monoglycerides. Oxidation and undesirable color effects can be minimized by working in vacuo or under an inert gas, and by using stainless steel reaction vessels. Monoglyceride concentrates can be produced by molecular or high-vacuum distillation.

10. Environmental Aspects

Crude oils and fats can be contaminated with traces of various substances such as metals (e.g., lead, arsenic, cadmium, selenium, mercury), chlorinated organic pesticides (DDT, dieldrin), mycotoxins (e.g., aflatoxins), and sulfur compounds. These trace contaminants are removed in the course of refining [55].

Wastewater from lye neutralization and from the barometric condensers of deodorizers can be discharged into communal sewage systems or surface waters only if certain limits for residual fat, pH, sediment, sulfate, and chemical and biological oxygen demand are met. Otherwise biological pretreatment is required. Since the cost of biological or other pretreatment of wastewater can be considerable, there has been a trend toward physical refining (i.e., refining without lye neutralization) by employing special degumming techniques, bleaching, and distillative deodorization.

Bleaching earth is normally extracted before being deposited or burnt. The extracted fats can be recycled.

Deodorizer distillates [55] can be used in animal feeds, as a source of vitamin E, for technical applications, or simply burnt.

11. Standards and Quality Control

Standardized methods for quality control have been issued by the following organizations:

Association Française de Normalisation (AFNOR), American Oil Chemists' Society (AOCS), Association of Official Agricultural Chemists (AOAC), American Society for Testing and Materials (ASTM), British Standards Institution (BSI), Deutsche Gesellschaft für Fettwissenschaft (DGF), Deutsches Institut für Normung (DIN), International Association of Seed Crushers (IASC), International Union of Pure and Applied Chemistry (IUPAC), International Standards Organization (ISO), the Netherlands Normalisatie Instituut (NNI), and the Fed-

eration of Oils, Seeds, and Fats Associations (FOSFA).

There is an increasing trend for the various national and international methods to be uniformly standardized as ISO procedures; these are generally adopted as official methods within the European Community.

The IASC (8 Salisbury Square, London EC 4P 4 AN, UK) has issued a list of associations dealing with or issuing standard forms of contract and/or quality standards for oilseeds, oils, and fats. This association has also drawn up a list of official institutions and associations that deal with or issue methods for grading, sampling, and preparing samples for analysis, as well as methods for analysis that are referred to in standard forms of contract or usually applied in the trade of oilseeds, oils, and fats.

11.1. Sampling

Correct sampling is a difficult process requiring careful attention; it must take into account that separation can occur during storage of fats and fatty products. Hulls, for example, tend to separate from oilseeds because of their lower density. Oils and fats tend to form a sediment of water and dirt; for this reason a representative average sample is often taken in bypass during pumping.

A special zone sampler consisting of a metal cylinder with a valve at both ends is often used for sampling the contents of a tank. The sampler is lowered into the tank, the valves being operated with a cord. Starting from the bottom of the tank, the oil is sampled at various depths up to the surface. Smaller containers (drums) are sampled with a tube or shutter scoop; solid fats in retail packs are sampled with a sampling scoop.

Special sample dividers are used for oilseeds. Sampling apparatus for bags includes sack-type spears or triers, cylindrical and conical samplers, and hand scoops. Shovels, scoops, cylindrical and conical samplers, or mechanical samplers are used for drawing small periodical samples from a flow of oilseeds. Shovels, quartering irons, or riffles are used for mixing and dividing.

Samples for analysis of oilseeds, expeller cakes, and meals should preferably be at least 2 kg, and of oils and fats at least 250 g. The samples should be homogenized immediately prior to analysis. Larger oilseeds are comminuted prior to analysis.

11.2. Raw Materials

Buying – selling contracts for oilseeds, crude oils, and fats normally specify a maximum permissible concentration of impurities. If this level is exceeded the buyer receives a discount. The key parameters in oilseeds are fat and moisture contents.

To determine the *fat content* of oilseeds, expeller cakes, and meals, the comminuted sample is extracted with a solvent and the fat taken up by the solvent is determined refractometrically, gravimetrically, densitometrically, or by the change in dielectric constant. The gravimetric methods are time-consuming but most reliable. Each method gives reproducible but different values, depending on the type of solvent (usually hexane or petroleum ether) and the extraction method. The fat content can also be determined directly without solvent extraction by nuclear magnetic resonance or by near infrared absorption.

According to ISO 659, the oilseeds are extracted with *n*-hexane or petroleum ether in a Bolton extractor. After extraction for several hours, the sample is removed from the extractor thimble, reground, and reextracted. This is repeated a third time. The extract is evaporated and the residual oil dried to constant weight at $103 \pm 2\,^{\circ}C$.

Unilever has developed a far quicker method which gives identical values to those obtained with the ISO method. The sample is first comminuted in a ballmill in the presence of petroleum ether, and then extracted for 2 h in a Bolton extractor.

When determining the fat content of fruit pulps and animal tissues, predrying of the substrate at 105 °C in vacuo is recommended. When extracting animal tissue polar solvents such as ether – HCl or ethanol – chloroform are used to facilitate liberation of fat from lipoprotein complexes present in aqueous dispersion.

Water and *volatile matter* are generally determined by weighing a sample before and after heating under standardized conditions, usually 103 °C. Crude oils are normally analyzed for water and volatile matter, color, particulate dirt,

phosphatides, and free fatty acids. Up to 0.5 % moisture and impurities are generally regarded as technically unavoidable. Inferior oils usually have a dark color and a high content of free fatty acids and oxidized components that is indicated by a relatively high absorption at 232 nm, high anisidine and totox numbers, and a high concentration of oxidized fatty acids. These analytical data give an approximate indication of the expected yield and quality of the fully refined product. Admixture can be detected within certain limits by determining the composition of fatty acids, sterols, and tocopherols. Very severe admixture can be detected by iodine value, refractive index, and saponification value.

11.3. Oils and Fats

11.3.1. Physical Methods

The *density* or *specific gravity* at a given temperature is determined by weighing a known volume, by determining the buoyancy, or by electromagnetic excitation of the natural frequency of the sample.

The *refractive index* is normally determined with an Abbe refractometer at 20 °C for oils which are liquid at this temperature and at 40, 60, or 80 °C for fats. The temperature coefficient is ca. 0.0036 K^{-1}. A correlation exists between refractive index and iodine value (see Section 3.8); for this reason the refractive index is often used to follow the course of hydrogenation.

Most oils and fats rotate *polarized light* by only a few tenths of a degree; higher values are observed with substituted fatty acids such a ricinoleic acid.

In melting a distinction is made between the slip point, the point of incipient fusion, and the point of complete fusion. The *slip point*, the usually cited melting point, is the temperature at which a sample plug placed in an open glass capillary begins to rise when gradually heated in a water bath or by other means. This method can be automated. The slip point value is influenced by the method of cooling used prior to melting. Whereas for conventional fats the sample is normally solidified by chilling the sample and capillary at − 10 °C for a few minutes, fats that exhibit distinct polymorphism, e.g., cocoa butter and substitutes, are conditioned at higher temperatures for up to 18 h.

The *point of incipient fusion* is the temperature at which a sample placed in a U-tube begins to flow on being warmed. The *point of complete fusion* is the temperature at which a sample becomes completely clear.

Flow and *drop points* are primarily of importance for technical greases and some plastic fats. They are determined in an Ubbelohde apparatus. Flow point is the temperature at which a drop begins to be clearly formed at the end of a thermometer, and drop point is the temperature at which the drop falls.

Dilatation, i.e., the increase in volume of a fat on passing from the solid to the liquid state at a given temperature, can be used to determine the concentration of solid components at a certain temperature (Solid Fat Index, SFI). This type of measurement has been replaced by the much quicker *nuclear magnetic resonance* method which is based on the difference between the response from the hydrogen nuclei in the solid phase and that from all the hydrogen nuclei in the sample.

Differential thermal analysis permits the quantification of changes in the solid phase of a fat on being heated. A sample is placed in a metal block which is heated at a constant rate. The difference between the temperature of the block and that of the sample is characteristic of crystal modifications occurring during melting [69].

On passing from the liquid to the solid state, the temperature remains constant for a certain period of time because of the liberated heat of fusion; with sufficient insulation an increase in temperature can be observed. The *titer value* of a fat is the maximum value to which the temperature rises in the cooling curve. Cooling curves are frequently used to check the purity of fats which consist predominantly of a few triglyceride types, e.g., cocoa butter.

The *cloud point* is the temperature at which an oil or molten fat begins to become turbid when cooled under controlled conditions. The temperature stability of an oil is normally assessed after keeping a carefully dried sample at 0 °C for 5 – 8 h.

The smoke, flash, and fire points of oils and fats are measures of their thermal stability when heated in air. Table 13 shows some typical data.

The *smoke point* is the temperature at which smoke is first detected in a standard apparatus with specially designed, draft-free illumination. The *flash point* is the temperature at which volatile products are evolved at such a rate that they can be ignited but do not continue to burn. The *fire point* is the temperature at which the production of volatile products is sufficient to support continuous combustion after ignition. The smoke point is important in the assessment of refined oils and fats used for deep frying. It is governed primarily by the free fatty acid content. The flash point is a measure of residual solvent in crude oils, although gas – liquid chromatographic methods are now generally preferred for this determination.

The *viscosity* of an oil can be determined in a flow (Engler), capillary (Ubbelohde), fall (Höppler), or shear (Haake) viscometer.

There are a number of different methods for determining the *color* of an oil or fat. In the Lovibond tintometer the color of the sample in a standardized cell with a length of 1″ (2.45 cm) or 5 1/4″ (13.3 cm) is matched – either manually or automatically – with the color of standard yellow, red, and blue color slides. Other colorimetric scales are based on standard iodine or potassium dichromate solutions. The most objective way of assessing color is to determine the absorption at specified wavelengths in the range 370 – 780 nm.

The characteristic absorption maxima of specific lipid groups in the infrared and ultraviolet ranges can be used qualitatively and quantitatively (see Section 3.8). Fatty acids with isolated double bonds such as linoleic, linolenic, and arachidonic acids do not exhibit specific UV absorption. After isomerization with alkali they can, however, be determined by the characteristic absorption maxima of the corresponding conjugated fatty acids. Infrared spectroscopy is used primarily for the identification of specific groups such as hydroxyl and trans double bonds.

Optical rotatory dispersion spectroscopy is used only in studies of biosynthesis and metabolism of lipids.

Mass spectroscopy, especially in combination with gas chromatography and other methods of separation, is often used to determine the structure of oxidation products and substituted fatty acids.

11.3.2. Chemical Methods

For preliminary identification and evaluation, determination of chemical data such as the iodine value (see below) and the fatty acid composition often suffice. In many cases, however, it is necessary to test for characteristic minor constituents directly or by specific chemical reactions. Table 23 gives some examples.

The complexity of oils and fats makes the determination of their precise composition difficult. For this reason analytical values are used to express certain properties. Analytical values in this sense are defined as the equivalent amounts of certain reagents which react with specific groups in the lipid molecules. Many of the older analytical values are no longer used because of the introduction of modern analytical techniques such as column, paper, gas – liquid, and high – performance liquid chromatography, and spectrophotometry. However, the principle of determining analytical values is still valid since it can authenticate and assess the quality of an oil or fat relatively quickly with modest laboratory facilities.

The *saponification value* is the number of milligrams of potassium hydroxide required to saponify (hydrolyze) 1 g of fat and is related to the molecular mass of the fat.

The *hydroxyl value* is expressed as the number of milligrams of potassium hydroxide required to neutralize the acetic acid needed to acetylate 1 g of fat.

The *carbonyl value* is defined as the number of milligrams of CO (carbonyl groups) per gram of fat. The basis for this value is the conversion of the carbonyl group into an oxime with hydroxylamine in alcoholic KOH:

$$RCO + NH_2OH \longrightarrow RC{=}NOH + H_2O$$

Hydroperoxides interfere with this determination.

The acidity of an oil or fat arises from free inorganic or organic acids. The *acid value* is defined as the number of milligrams of potassium hydroxide required to neutralize 1 g of fat. The content of free fatty acids (ffa) expresses how many parts of free fatty acids are contained in 100 parts of fat. This content is – depending on the type of oil or fat – expressed as % oleic acid

Table 23. Detection of oils and fats

Oil/Fat	Characteristic constituent	Specific reaction or detection procedure	Limit of detection	Remarks
Animal fats	cholesterol	isolation of sterols from the unsaponifiable matter by TLC or HPLC, and separation by HPLC, TLC, or GLC	1 % in vegetable oils and fats	Vegetable oils and fats contain traces of cholesterol in addition to phytosterols while in animal fats only cholesterol but no phytosterols have been found.
	branched $C_{13}-C_{17}$ fatty acids and odd-numbered, unbranched $C_{11}-C_{19}$ fatty acids	GLC of fatty acid methyl esters	ca. 2 % in vegetable oils and fats	The branched fatty acids may have to be concentrated, e.g., by urea adduct formation.
Lard	palmitic acid in the glyceride 2-position	isolation of the glyceride fraction with 1 saturated and 2 unsaturated fatty acid groups, followed by determination of the fatty acid composition in the glyceride 2-position	1 % lard in tallow	Determination of the fatty acid composition in the 2-position without prior glyceride fractionation gives a significantly higher limit of detection.
Partially hardened and unhardened marine oils	highly unsaturated $C_{20}-C_{24}$ fatty acids	Tortelli–Jaffe reaction (green coloration with bromine in chloroform/acetic acid) GLC of the fatty acid methyl esters	ca. 2 % in other oils and fats	Not strictly specific; highly unsaturated vegetable oils can also react.
Vegetable oils and fats	phytosterols	isolation of sterol esters and separation as sterols by TLC, HPLC, and GLC	ca. 2 % in animal fats	Sterols occur in vegetable oils and fats in the free and esterified form, while in animal fats they are only present in the free form.
Castor oil	ricinoleic acid	TLC; IR spectroscopy	ca. 1 % in other oils and fats	Hydroxy fatty acids can be formed during autoxidation of oils and fats.
Coconut oil and palm kernel oil	lauric acid	GLC of the fatty acid methyl esters	ca. 2 % in other vegetable oils except oils and fats rich in lauric acid, e.g., babassu fat	
Cottonseed oil and other oils of the malvaceae, tiliaceae, and bombaceae families	malvalic acid	Halphen reaction (red coloration on heating with sulfur in CS_2)	depending on extent of refining	Hardened cottonseed oil does not give this reaction; malvalic and sterculic acid are converted into saturated, branched fatty acids during hardening.

Table 23. Continued

Oil/Fat	Characteristic constituent	Specific reaction or detection procedure	Limit of detection	Remarks
Crude palm oil	α- and β-carotene	isolation from nonsaponifiable matter by HPLC		Indicative of distillative or other heat treatment.
Peanut oil	lignoceric and arachidic acid	GLC of the fatty acid methyl esters	4	Hardened marine oils and certain vegetable oils also contain higher molecular mass fatty acids.
Olive oil	α-tocopherol	isolation and separation by HPLC	ca. 5 % other oils in olive oil	
Partially hardened fats	trans fatty acids	IR spectroscopy	ca. 2 % in vegetable oils	Animal fats contain up to 10 % trans fatty acids.
Rapeseed oil	erucic acid	GLC of the fatty acid methyl esters	ca. 1 % of "high erucic acid" rapeseed oil in other vegetable oils	Admixture with "low erucic acid" rapeseed oil cannot be detected satisfactorily this way. Marine oils also contain erucic acid.
	brassicasterol	isolation and separation of sterols by TLC, HPLC, and GLC	ca. 5 % in other vegetable oils	Independent of erucic acid content.
Sesame oil	sesamol and sesamin	Baudouin reaction (red coloration with furfural and HCl)	ca. 0.5 % in other oils and fats	
Soybean oil	linolenic acid	GLC of the fatty acid methyl esters	ca. 10 % in e.g., sunflower oil	
	δ-tocopherol	isolation and separation by HPLC	ca. 5 % in e.g., sunflower oil	
Teaseed oil		Fitelson test (modified Liebermann – Burchard test)	e.g., 5 % in olive oil	
Tung oil	eleostearic acid	GLC of the fatty acid methyl esters	ca. 1 % in other oils and fats	

(M_r 282), % palmitic acid (M_r 256), or % lauric acid (M_r 200). If not specified, it is calculated as oleic acid.

Peroxides are determined iodometrically according to Wheeler (cold) or Sully (hot) and are expressed as milliequivalents of active oxygen per 1000 g of fat. The peroxide value can also be expressed in millimoles per kilogram (Lea value, 1 mequiv/kg = 0.5 mmol/kg) or in milligrams per kilogram (1 mequiv/kg = 8 mg/kg). It is important to use fresh reagents and to exclude oxygen as far as possible during the determination.

The reaction with anisidine is often used to determine the carbonyl compounds produced during autoxidation. The *anisidine value* is defined as 100 times the absorption of a 1 % sample solution in a 1-cm cell after reaction with anisidine. This value has been recommended for monitoring the refining of oils and fats. It is also used in combination with the peroxide value to characterize the overall autoxidative state of an oil or fat (*totox value*):

$$\text{Totox value} = 2 \times \text{peroxide value} + 1 \times \text{anisidine value}$$

The *iodine value* denotes the percentage by weight of iodine bound by 100 g of fat and is an approximate measure of the degree of unsaturation. The usual method is that of Wijs. The rate of addition of iodine to double bonds depends on their distance from the carboxyl group. Conjugated unsaturated fatty acids are only partially halogenated; substituted fatty acids such as keto acids and cyclic acids can also react. Trans fatty acids react more slowly than the cis isomers.

The *oxidative stability* of oils and fats is determined by their composition and their previous history. A number of empirical methods have been developed to express oxidative stability [70]. These tests are performed at elevated temperature and do not necessarily correlate with organoleptic stability at ambient temperature. The most frequently practiced methods are the Schaal test and the Swift test (or Active Oxygen Method); automated versions of the latter are popular, e.g., the Rancimat apparatus.

The *moisture content* can be determined by weighing before and after drying or by codistillation with toluene. It is most conveniently determined by the Karl Fischer titration, which is based on the following reaction:

$$2\,H_2O + SO_2 + I_2 \longrightarrow H_2SO_4 + 2\,HI$$

Impurities such as dirt and seed particles are not dissolved on treating the sample with petroleum ether or hexane and can be collected and weighed as filter residue.

Traces of *residual solvent* are best determined by gas chromatography, either by direct injection or after enrichment by the so-called headspace technique [71].

Nonsaponifiable matter is defined as that material which is a soluble constituent of the fat and which remains insoluble in the aqueous phase after saponification of the fat and can be extracted with petroleum ether or diethyl ether; diethyl ether tends to give higher values. Nonsaponifiable matter consists primarily of sterols, alcohols, hydrocarbons, and vitamins.

Oxidized fatty acids contain one or more hydroperoxide, hydroxyl, or keto groups in the fatty acid chain and can be determined by their reduced solubility in petroleum ether. Only part of the oxidized fatty acids are detected by this type of analysis. Thus, the separation of fats into polar and nonpolar fractions on silica gel tends to be preferred when, for example, characterizing used frying fats [72].

To determine *resin acids* in the presence of fatty acids, the sample is esterified with methanol in the presence of an acid catalyst; resin acids escape esterification.

Inorganic acids can be detected by extracting the sample with hot water and testing the aqueous extract with methyl orange.

Free alkali can similarly be detected by dissolving the sample in ether – ethanol and adding phenolphthalein (red coloration). Traces of soap can be detected down to 10 ppm by dissolving the sample in ether – ethanol, adding bromophenol blue (which gives a green-blue color in the presence of soap), and titrating with very dilute HCl.

Many crude seed oils contain considerable concentrations of *phosphatides*. These can be determined by dry digestion of the sample with magnesium oxide and photometric determination of the resulting phosphate after addition of molybdate [73]. An alternative is the direct determination of phosphatides by atomic absorption or plasma emission spectroscopy.

Methods for determining traces of *mineral oil* in edible oils are based on the fluorescence of mineral oils, their insolubility in acetic anhydride, and the fact that they are not retained on alumina. Headspace gas chromatography is also used.

The gas chromatographic determination of the *fatty acid composition* of an oil or fat has replaced the time-consuming, chemical techniques of fractionating fatty acids into single components or groups. Analytical values such as the Reichert–Meissl, the Polenske, the Kirchner, and the butyric acid number (as measures of the concentration of lower molecular mass or steamvolatile fatty acids) are now virtually obsolete. Prior to gas chromatographic analysis, the fatty acids are converted into their methyl esters either by direct transesterification of the sample with methanolic KOH (acid values <2) or by saponification (acid values >2) followed by esterification of the fatty acids with methanol in the presence of BF_3. Full details of these procedures and of the various types of columns, column packings, and detectors are given in ISO 5508/5509. If a marker fatty acid is used as an internal standard, quantitative determination of the total amount of monomeric, nonoxidized fatty acids is possible; nonsaponifiable matter, oxidized, and polymerized fatty acids are retained on the gas chromatographic column.

Polymeric fatty acids are conveniently determined by special high-performance liquid chromatography (HPLC) or gel permeation chromatography [74].

The *glyceride structure* may have to be determined to authenticate an oil or fat. The methods for determining positional isomers are based on fractional crystallization, selective oxidation, chromatographic separation, or enzymatic hydrolysis of the fatty acid in the 2-position; they are normally too expensive for routine control unless specialty products are involved.

Mono- and diglycerides are formed by hydrolysis of fats and therefore occur in higher concentrations in fats from damaged seeds. Mono-, di-, and triglycerides can be separated by column or thin-layer chromatography. 1-Monoglycerides can be determined directly in fats by oxidative fusion with periodic acid:

$$RCOOCH_2CHOHCH_2OH + H_5IO_6 \longrightarrow$$
$$HCHO + RCOOCH_2CHO + HIO_3 + 3\,H_2O$$

Monoglycerides can be isomerized into the 1-isomers prior to addition of periodic acid by treating the sample with perchloric acid.

12. Storage and Transportation [75]

Crude Oils and Fats. If crude oils and fats are to be stored for a long time, removal of insoluble impurities by sedimentation, filtration, or centrifugation is advisable. Seed particles and cell fragments contain fat-splitting enzymes, which can gradually hydrolyze glycerides in the presence of moisture and produce an increase in free fatty acid concentration. Proteins are good nutrients for microorganisms.

Further measures for avoiding undue quality deterioration include drying the crude oil to less than 0.2 % moisture and storage without heating; consistent fats should be stored at not more than 10–15 °C above the melting point. Frequent pumping should be avoided to prevent saturation of the oil with air and consequent autoxidation. The addition of antioxidants is useful primarily for animal fats; most vegetable oils contain sufficient concentrations of natural antioxidants. Most crude vegetable oils can be stored for some months without significant loss in quality if the above precautionary measures are observed. Animal fats can be stored for only relatively short periods of time without loss in quality. Continual monitoring of the acid value, peroxide value, and other data that characterize the state of oxidation during storage is recommended.

Raffinates. Since natural antioxidants, such as tocopherols, phenols, and synergists, are partially removed during the refining process, semi- and fully refined oils often have lower oxidation stability than the crude oils. This is especially true for oils with a relatively high content of polyunsaturated fatty acids. Therefore, raffinates must be protected as far as possible from light, air, moisture, relatively high temperatures, and trace metal prooxidants if they are to be stored for long periods.

Raffinates are best stored in closed containers with a relatively small ratio of surface area to volume in order to minimize access and infusion of air. Any heating should be uniform without local overheating; the temperature should not be

higher than 10 °C above the melting point. Aeration can be further reduced by using a bottom-loading pipe and a nitrogen atmosphere during both storage and transportation. Immediately after deodorization, nitrogen should be introduced into the suction side of the loading pump that feeds the storage or transport vessels.

The storage containers are preferably made of aluminum or stainless steel, although mild steel can be used if access of air is limited and if cooling is adequate. Raffinates can be kept stored in large tanks for several weeks without an increase in peroxide value; however, the peroxide value tends to increase each time the oil is pumped. Raffinates are transported in bulk in ships and trucks, in drums, tins, and bottles; consistent fats can also be transported in block or powder form if the melting point is sufficiently high.

13. Individual Vegetable Oils and Fats

Vegetable oils and fats are normally divided into fruit pulp fats and seed oils. Although there are few fruit pulp fats (e.g., palm oil and olive oil), the number of seed oils is considerable. Seed oils can be conveniently subdivided according to their characteristic fatty acids:

1) Lauric acid oils (e.g., coconut and palm kernel oil)
2) Palmitic – stearic acid oils (e.g., cocoa butter)
3) Palmitic acid oils (e.g., cottonseed and corn oil)
4) Oleic – linoleic acid oils (e.g., sunflower and linseed oil)
5) Leguminous oils (e.g., soybean and peanut oil)
6) Cruciferous oils (e.g., rapeseed oil)
7) Conjugated oils (e.g., tung oil and oiticica oil)
8) Substituted fatty acid oils (e.g., castor oil)

13.1. Fruit Pulp Fats

Palm oil and olive oil are the most important products within this group.

13.1.1. Palm Oil [76]

Palm oil [*8002-75-3*] is obtained from the fruit pulp of the oil palm (*Elaeis guineensis*). The fruit bunches, weighing 10 – 25 kg, contain 1000 – 2000 plum-sized fruits which are dark red because of their carotene content. The fruits contain 35 – 60 % oil, depending on the moisture content. The oil palm is native to West Africa, and is extensively cultivated in Malaysia, Indonesia, and Central Africa. The oil yield has been increased to 4.5 t of oil per hectare and year by the introduction of insect pollination and by selecting and cloning high-yielding cultivars. Malaysian palm oil production was 4.13×10^6 t in 1985 and is expected to reach 6×10^6 t/a by 1990.

Saponification value	195 – 205
Iodine value	44 – 58
Nonsaponifiable matter	0.5 %
mp	36 – 40 °C
n_D^{40}	1.453 – 1.456
Carotene	500 – 2000 ppm

For fatty acid composition see Tables 1 and 2.

Palm oil contains up to 40 % oleodipalmitin, consisting primarily of 2-oleodipalmitin.

Production. The fresh palm fruits contain very active fat-splitting enzymes (lipases), which must be deactivated as quickly as possible prior to isolating the oil. Since lipases are particularly active in damaged fruits, the whole fruit bunches are sterilized by heating with live steam in autoclaves; this deactivates the enzymes and loosens the fruit from the bunches.

The sterilized fruit bunches are threshed in a rotary drum stripper consisting of longitudinal channel bars; the fruit falls through whereas the empty bunch stem is retained in the drum. The separated, sterilized fruit is then converted into an oily mash by a mechanical stirring process known as digestion. The digested fruit mass is passed through screw presses, and the liquor from the press is clarified by static settling or by using decanter centrifuges. After washing with hot water and drying, the oil can be stored and transported.

High-grade palm oil contains ca. 3 % free fatty acids, inferior grades up to 5 %. Crude plantation oils obtained from palm fruits processed

under conditions that minimize autoxidation and lipolysis contain ca. 2 % free fatty acids and can be readily bleached; such oils are traded as super prime bleachable (SPB) grades.

Refining. Lye neutralization of palm oil may entail relatively high losses of neutral oil since inferior crude oils contain high concentrations of mono- and diglycerides, which exert a strong emulsifying effect. Palm oil is therefore often neutralized by distillation at temperatures up to 270 °C and 0.5 – 0.8 kPa (5 – 8 mbar) after pretreatment with phosphoric or citric acid and bleaching earth to remove foreign matter and traces of copper and iron compounds. During distillative neutralization (stripping), the oil is also bleached (i.e., heat-bleached), since carotenes are decomposed and removed. The carotenes in palm oil mainly consist of α-and β-carotene, with lower concentrations of γ-carotene, lycopene, and xanthophylls.

Distillative neutralization can be performed under conditions that simultaneously deodorize the oil. For very light raffinates, distillative neutralization is often followed by posttreatment consisting of a lye wash, bleaching with earth, and deodorization. Color and stability are largely a function of the quality of the crude oil. "White" palm oil, e.g., for biscuit fats, can generally only be made from crude SPB oils and by using fairly large amounts of bleaching earth. Bleaching with oxidizing agents, with air injected at 110 – 115 °C, or with activated earth at 140 – 160 °C is used only for technical applications. Palm oil can be effectively decolorized by mild hydrogenation at temperatures below 100 °C (hydrobleaching).

Palm oil can be separated into a solid and a liquid fraction. Two-stage cooling to 32 – 34 °C and 25 – 27 °C followed by separation over filter presses yields 20 – 25 % palm stearin, *mp* 50 – 52 °C, and 75 – 80 % liquid palm olein. The liquid glycerides can be separated from the solid fraction by centrifugation after addition of surfactant solutions. Fractionation in the presence of solvents (acetone, hexane) gives 10 % of a stearin melting at ca. 55 °C, 60 % olein, and 25 – 30 % of an intermediate fraction with properties similar to those of cocoa butter. The yield of the intermediate fraction can be increased to ca. 50 % by interesterification of the combined stearin and olein fractions followed by repeated fractionation.

Use. Palm oil is used predominantly for edible purposes. Refined palm oil is used extensively in shortenings and margarines. Carotene concentrates from crude oil have been largely replaced by synthetic carotene as coloring agents for margarines.

Palm stearin can be used in margarine and shortening blends whereas palm olein is used primarily in liquid frying fats and shortenings.

Technical applications of palm oil include tempering of metal and production of soap.

Other Palm Oil Varieties. These are commercially relevant only in their countries of origin. Tucum oil (saponifaction value 200, iodine value 40) is obtained from the fruit pulp of *Astrocaryum vulgare*, a palm growing in Central America.

13.1.2. Olive Oil

Olive oil [*68153-21-9*] is obtained from the fruit of olive trees (*Olea oleaster, Olea europaea oleaster*) and some related varieties such as *Olea americana* which is grown in South America.

Saponification value	185 – 196
Iodine value	80 – 88
Nonsaponifiable matter	<1.4 %
mp	−3 °C
n_D^{25}	1.466 – 1.468

For fatty acid composition see Tables 1 and 2.

Olive oil has a yellow to greenish-yellow color and becomes cloudy below −5 °C. Varieties with a higher cloud point can be made by winterization. The glycerides consist of 45 – 60 % monosaturated dioleins, 25 – 34 % dioleolinolein, and 4 – 29 % triolein. Saturated triglycerides are present at <1 %. The nonsaponifiable material contains saturated and unsaturated hydrocarbons, including 0.1 – 0.7 % squalene.

Production. The quality of olive oil depends on the ripeness of the olives, the type of harvesting (picking, shaking), intermediate storage, and type of processing. Olives contain 38 – 58 % oil

and up to 60 % water. Ripe olives should be processed as quickly as possible since lipases in the pulp cause rapid hydrolysis of the oil, impairing its quality for edible purposes. Top-grade oils are made from fresh, handpicked olives by comminution, pasting, and cold pressing.

Traditionally, olives were ground into a paste with stone mills; today modern milling equipment is used. Milling is followed by mashing, possibly with addition of salt. The pulp is then pressed and the press oil clarified by settling or centrifuging. Open-cage presses are being replaced by continuous screw expellers. The mashed pulp can also be separated in a horizontal decanter, the crude oil being recentrifuged after addition of wash water. An alternative is the use of machines to remove the kernels from the pulp; the residue is separated in self-discharging centrifuges.

Cold pressing, which yields vierge grades (also referred to as virgin, Provence, or Nizza oil), is generally followed by warm pressing at ca. 40 °C, which gives an oil with a less delicate flavor. The yields depend on the equipment used. The press cake (pomace) contains 8 – 15 % of a relatively dark oil, called Sanza or Orujo, which can be extracted with hexane and is used for technical purposes; after refining it is also fit for edible consumption.

Olive kernel oil is obtained by pressing and solvent extraction of cleaned kernels. It is similar to olive oil but lacks its typical flavor.

Use. Cold-pressed olive oil is a valuable edible oil. Trade specifications are based primarily on the content of free fatty acids and flavor assessment. In some countries, warm-pressed olive oil with a high acidity is refined by neutralization, bleaching, and deodorization, and flavored by blending with cold-pressed oil.

Testing for Adulteration. Because of its high price, olive oil is sometimes admixed with other oils. Some oils can be detected by specific color reactions: cottonseed oil by the Halphen test, sesame oil by the Baudouin reaction, teaseed oil by the Fitelson test (see Table 23). Gas chromatographic determination of the fatty acid and sterol composition is generally used to quantify the degree of adulteration. Olive-pomace oil and re-esterified olive oil, obtained by esterification of olive oil fatty acids or Sanza or Orujo oil with glycerol, can be detected by the glyceride composition.

13.1.3. Avocado Oil [77]

Avocado oil is isolated from the pulp of the pearlike fruit of the tree *Persea gratissima* L. growing in Southern Europe, South Africa, the Middle East, and Central America. Its composition and properties are similar to those of olive oil (see Tables 1 and 2). The oil is used in cosmetics; in California smaller quantities of avocado oil are used as special salad oil. The avocado fruit weighs up to 1.5 kg and contains 40 – 80 % oil in dry matter. World production of avocado fruit is ca. 1.5×10^6 t/a, but only a small fraction is used for oil production.

13.2. Seed-Kernel Fats

Oilseeds are the major source of oils and fats.

13.2.1. Lauric Acid Oils

Coconut, palm kernel, and babassu oil are the most important lauric acid oils. They contain >40 % of lauric acid and ca. 15 % of myristic acid.

13.2.1.1. Coconut Oil [76]

The coconut palm (*Cocos nucifera* or *Cocos butyracea*) is cultivated in coastal areas around the world within 20 ° of either side of the equator. The Philippines, Indonesia, Southern India, Sri Lanka, Equatorial Africa, and the West Indies are important producers. Around 1820 coconut oil [*8001-31-8*] was introduced to Britain (vegetable butter).

Saponification value	250 – 262
Iodine value	7 – 10
Nonsaponifiable matter	0.15 – 0.60 %
mp	20 – 28 °C
n_D^{40}	1.448 – 1.450

For fatty acid composition see Tables 1 and 2

The glycerides contain 50 – 60 % caprylolauromyristin and up to 20 % myristodilaurin in addition to smaller concentrations of laurodimyristin.

Production. In plantations the coconut palm reaches a height of 30 m and from its 6th to 30th years annually yields 50 – 70 coconuts with a diameter of 10 – 12 cm. The hard shell, covered by a fibrous husk, encloses the white endosperm tissue 1 – 2 cm thick, the copra. To obtain a light, flavor-stable coconut oil, the fresh copra with a water content of 60 – 70 % is dried in the sun or with hot air. This treatment prevents bacterial decomposition and lipolysis of the fat. Dry copra contains 60 – 67 % oil.

The dried copra is processed in an oil mill in two steps. About two-thirds of the oil is first obtained by expelling broken and rolled copra in continuous screw presses. The residual fat content of the expeller cake can be reduced to ca. 5 % by high-pressure expelling and to 2 – 4 % by subsequently extracting the expeller cake with hexane.

In order to obtain an edible oil of good quality, the crude coconut oil must be neutralized, bleached, and deodorized. Normally, the crude oil contains ca. 5 % free fatty acids but it can be lye-neutralized without great loss of neutral oil. The neutralized, washed, and dried oil contains only small amounts of pigments, phosphatides, and other constituents. It is decolorized with 1 – 2 % of bleaching earth and 0.1 – 0.4 % of activated charcoal. Activated charcoal also serves to remove polycyclic aromatic hydrocarbons deposited on the copra by drying with flue gases [53]. Crude coconut oil with a relatively high content of free fatty acids can be advantageously neutralized and deodorized by distillation after pretreatment with phosphoric acid and bleaching earth – activated charcoal.

Uses. Coconut oil is used for cooking, and is also an important component of vegetable margarines. Because of its high latent heat of fusion, it produces a pronounced cooling effect in the mouth on melting. This effect also makes it a valuable fat for biscuit filling, confectionery products, and confectionery coatings (couvertures). Coconut oil can undergo enzymatic hydrolysis in foods containing relatively high concentrations of water leading to so-called perfume rancidity. This reaction can be counteracted by incorporating at least 30 % sugar or by drying. Coconut oil has a high resistance to oxidative deterioration.

Coconut stearin, *mp* 27 – 32 °C, and coconut olein can be obtained by fractional crystallization and pressing of prerefined coconut oil. Coconut stearin is used in couverture for confectionery products.

Hydrogenated coconut oil (iodine value 2 – 4, *mp* 30 – 32 °C) is produced from prerefined coconut oil with fresh nickel catalyst at 140 – 180 °C. In the summer months it is often used in admixture with unhardened coconut oil to raise the melting point of couvertures and similar products.

Crude coconut oil, meeting certain color specifications, is also used in the manufacture of special soaps.

13.2.1.2. Palm Kernel Oil [76]

Palm kernel oil [*8023-79-8*] is derived from the kernels of the oil palm (*Elaeis guineensis*) (see Section 13.1.1).

Saponification value	242 – 254
Iodine value	16 – 19
Nonsaponifiable matter	0.2 – 0.8 %
mp	23 – 30 °C
n_D^{40}	1.449 – 1.452

For fatty acid composition see Tables 1 and 2

The properties of palm kernel fat are very similar to those of coconut oil. However, it contains more oleic acid and only half as much C_8 and C_{10} fatty acids. The glycerides of palm kernel oil consist of 60 – 65 % trisaturated, ca. 25 % disaturated – monounsaturated, and 10 – 15 % monosaturated – diunsaturated components. Its stability is similar to that of coconut oil.

Production. The palm nuts are separated by air classifiers from the fibers of the press cake obtained on pressing palm fruit (see Section 13.1.1). After drying in silo dryers, the nuts are cracked with centrifugal crackers, and the shell is separated from the kernel with air and water separation systems. The kernel, 1 – 2 cm in size, is dried from an initial moisture content of 20 – 25 % to about 4 – 7 %; it then contains 44 – 57 % oil. Following cracking and rolling, the palm kernels are passed through a screw expeller. The residual oil in the press cake can be further reduced by high-pressure expelling or, more commonly, by extraction with hexane.

Crude palm kernel oil often has a higher free fatty acid content than coconut oil (up to 15 %, calculated as oleic acid). Palm kernel oil with a free fatty acid content <5 % can be lye-neutralized without significant neutral oil losses. At higher contents of free fatty acids, distillative neutralization (possibly followed by lye post-neutralization) is generally preferred. Treatment with 1 – 2 % activated bleaching earth yields a light, yellowish oil. Deodorization generally requires a longer period of time than for coconut oil in order to obtain a stable, bland raffinate.

Use. Top-grade palm kernel raffinates are used in couvertures and margarines. Palm kernel stearin and olein are obtained by fractional crystallization of prerefined palm kernel oil at ca. 25 °C. Palm kernel stearin, *mp* 30 – 32 °C, is often used as such, or blended with coconut stearin, as a filling mass or couverture for confectionery products. Hydrogenated palm kernel oil (*mp* 39 °C, iodine value 1) is made in the same way as hydrogenated coconut oil and is mostly used in the confectionery trade. The melting point of hydrogenated palm kernel oil can be reduced from 39 °C to 33 – 35 °C by interesterification. Interesterified, hydrogenated palm kernel oil increases the range of special tailor-made products for application in confectionery products.

13.2.1.3. Babassu Oil and Other Palm Seed Oils

The babassu palm (*Orbygnia speciosa, Attalea funifara*) is a native of the great forest regions of the Brazilian states Maranhão, Piauí, Pará, and Minas Geraes. The number of babassu trees in these forests is estimated at $>10^9$. Collecting and transport of the babassu nuts to the oil mills and removal of the extremely hard shell prior to expelling make it difficult to exploit this interesting source of lauric oil. A bunch holds 200 – 600 fruits; 1 t of fruit yields about 125 kernels containing 63 – 70 % fat after drying to ca. 4 % moisture. The fat can be isolated by expelling and subsequent extraction with hexane.

Saponification value	242 – 253
Iodine value	10 – 18
Nonsaponifiable matter	0.2 – 0.8 %
mp	22 – 26 °C
n_D^{40}	1.449 – 1.451

For fatty acid composition see Tables 1 and 2

Use. Refined babassu oil is known in South America as an edible fat. In European countries it is used in place of palm kernel oil in margarine blends. The export of babassu kernels is only of minor economic importance; total production is likely to be around 150 000 t/a.

Other palm seed oils are used as edible fats in their countries of origin and do not play a role in international trade. Some of their properties are listed in Table 24. Cohune oil is obtained from the kernels of the cohune palm (*Attalea cohune*), a native of Mexico and Honduras. Its properties are similar to those of coconut oil. Murumuru oil, somewhat harder than coconut oil, is contained in the kernels of the palm *Astrocaryum murumuru*, which is found in the Northern provinces of Brazil. It contains ca. 40 % lauric acid, 35 % myristic acid, and only little caprylic and capric acids. Ouricuri oil, from the kernels of the Brazilian palm *Syagrus coronata*, has a lower melting point than murumuru oil. It contains 45 % lauric acid and 10 % myristic acid in addition to 20 % fatty acids with 6, 8, and 10 carbon atoms. The kernels of *Astrocaryum tucuma*, a native of Guyana, Venezuela, and Northern Brazil, yield tucum oil.

13.2.1.4. Other Sources of Lauric Acid Oils

Up to 43 % of lauric acid is contained in the seed oil of the evergreen laurel tree (*Laurus nobilis*), from which the name of this acid was derived. Laurel oil contains about 30 % trilaurin; it has no commercial importance.

The seed oils of *Myristica* species contain relatively high concentrations of myristic acid. Nutmeg butter [*8008-45-5*] is made by expelling ground and boiled seed kernels of *Myristica officinalis*; it contains 39 – 76 % myristic acid. *Myristica otoba* yields otoba fat. Ucuhuba fat is obtained from *Virola surinamensis*, a native to Brazil. Dika fat is contained in the seed kernels of *Irvingia gabonensis* and *I. barteri*, native to

Table 24. Properties and analytical data of seed oils of some South American palm varieties

West Africa. None of these fats is involved in international trade.

Cuphea is a herbaceous, annual plant, native to Mexico and also found in Northern Brazil and Nicaragua. The seed oil contains various medium-chain fatty acids which, depending on the species, account for 40 – 80 % of the total fatty acids. Cuphea oil could be a substitute for coconut and palm kernel oil and serve as a natural source of capric acid; agronomic research is directed toward adaptation and yield improvement of *Cuphea* [78].

13.2.2. Palmitic – Stearic Acid Oils

13.2.2.1. Cocoa Butter

Cocoa butter is the seed fat of *Theobroma cacao* L., a tree reaching a height of 9 m, which is cultivated in many tropical countries (→ Chocolate, Chap. 6.1.). The cocoa tree is grown mainly in West Africa (Ivory Coast, Nigeria) and South Africa (Brazil). The world production of cocoa beans is in the order of 1.3×10^6 t/a.

Saponification value	190 – 200
Iodine value	35 – 40
Nonsaponifiable matter	0.2 – 0.5 %
mp	28 – 36 °C
n_D^{40}	1.453 – 1.458

For fatty acid composition see Tables 1 and 2

Cocoa butter has a pleasant aromatic flavor and keeps well. The cocoa butter glycerides are hard and brittle up to about 28 °C and melt in a range of 4 – 5 °C with a pronounced oral cooling effect. The melting point of cocoa butter depends on the type and length of tempering. After rapidly cooling to 0 – 5 °C, cocoa butter melts at 26 – 30 °C, whereas the melting point increases to 32 – 35 °C after tempering for 40 h at 28 °C. The dilatation curve (plot of solids content at different temperatures) is very steep (see Fig. 2).

The glycerides of cocoa butter consist roughly of 2 % trisaturated compounds, 14 % 2-oleodipalmitin, 40 % 1-palmito-3-stearo-2-olein, 27 % 2-oleodistearin, 8 % palmitodiolein, and 8 % stearodiolein.

Production. Cocoa butter is isolated from cocoa beans by fermentation, roasting, dehulling, grinding, and expelling (→ Chocolate, Chap. 6.1.). The fat content of dehulled cocoa beans is about 54 – 58 % in dry matter. In some countries the fat obtained from nondehulled cocoa beans by expelling or solvent extraction may also be called cocoa butter.

Use. Cocoa butter is used extensively in the production of chocolate and other confectionery products, and to a lesser extent in the pharmaceutical and cosmetics industries.

Test for Adulteration. Because of its high price, cocoa butter is sometimes admixed with press or extraction fat from damaged cocoa beans or byproducts, animal fats, coconut oil and stearin, palm oil and palm oil fractions, or hydrogenated vegetable or marine oils.

Extraction cocoa butter can be identified by its relatively dark color, by its strong fluorescence under ultraviolet light, by various color reactions, and by its behavior in simple tests such as the "smear test" (extraction fat tends to smear while authentic cocoa butter tends to disintegrate into small, hard pieces). In addition, extraction fat has a higher content of nonsaponifiable matter (cocoa butter contains 0.2 – 0.5 %, extraction fat 1.9 – 2.8 %, fat from cocoa bean hulls about 7.5 % nonsaponifiable matter) and a higher content of linoleic acid (10 – 29 % compared to 2 – 4 % in authentic cocoa butter).

Animal fats such as tallow and hydrogenated fish oils can be detected by gas chromatographic analysis of the fatty acid composition and by their cholesterol content. Hydrogenated vegetable oils can be recognized by their content of trans fatty acids. Coconut oil and similar oils can be detected by their concentrations of C_8, C_{10}, C_{12}, and C_{14} fatty acid groups. Addition of cocoa butter-like fats such as fractions of Borneo tallow, illipé fat, shea butter, and palm oil can sometimes be detected by their concentration of terpene alcohols. Gas chromatographic analysis of chocolate fat triglycerides can detect so-called cocoa butter equivalents in cocoa butter and certain types of chocolate; this technique can be augmented by analyzing the fatty acid composition at the 2-position [79].

13.2.2.2. Shea Butter, Borneo Tallow, and Related Fats (Vegetable Butters)

Shea butter, also known as Karité butter or Galam butter, is obtained from the seeds of a tree growing mainly in West Africa (*Butyrospermum parkii*). Plantations tend to be uneconomic since shea nuts can be harvested only after the tree is about 15 years old.

Shea butter is similar to cocoa butter (see Table 25). The content of nonsaponifiable matter, which contains rubber-like hydrocarbons such as kariten [$(C_3H_8)_n$, *mp* 63 °C], can be as much as 11 %.

The kernels can be readily separated from the fruit and the thin hulls. In Africa they are ground, boiled, and the fat is skimmed off. The commercial production of shea butter by expelling in continuous screw presses is difficult and requires special processing conditions. The green-brown crude fat can be neutralized only with considerable loss of neutral oil.

Refined shea butter can be used as an edible fat. The stearin fraction, primarily 2-oleodistearin, which can be obtained by crystallization and removal of the liquid fraction, is a valuable cocoa butter substitute. The export quantities (from Nigeria, Dahomey, Upper Volta) amount to ca. 50 000 t/a.

Borneo tallow (tengkawang tallow) is derived from *Shorea stenoptera*, a plant growing in the East Indies and Malaysia; there are about 100 different species including *S. gysbertsiana, S. palembassica,* and *S. seminis*. The proportions of component fatty acids in these species are very similar. The size of nut varies considerably from one variety to another, and only a few are worth harvesting. Borneo tallow resembles cocoa butter chemically and physically more closely than any other fat. For this reason it is used in preparing cocoa butter equivalents or extenders.

Sal butter is derived from *Shorea robusta*, commonly known as the sal tree, found extensively in parts of Northern and Central India. Illipé fat is derived from the group of Madhuca seed fats (also known as Bassia seed fat) and is itself produced from the Indian plant *Madhuca longifolia*. Another Indian plant, *Madhuca latifolia,* is the source of mowrah fat which is very similar in composition. Illipé and mowrah fats contain sufficient unsaturated fatty acids to make them resemble shea butter rather than the firmer cocoa butter and Borneo tallow. Illipé and mowrah fats are used principally in Asia for technical purposes but also for edible purposes when fully refined. Both fats are used to prepare cocoa butter extenders. Katiau fat is derived from the plant *Madhuca mottleyana,* and phulwara butter (Indian butter) from *M. butyracea.*

For properties of the various vegetable butters see Table 25 [80].

13.2.3. Palmitic Acid Oils

The oils in this group have a relatively high content of palmitic acid, mostly above 10 %. Cottonseed oil and some cereal oils are the most important representatives.

13.2.3.1. Cottonseed Oil

Cottonseed oil [*8001-29-4*] is obtained from the seeds of different varieties of cotton (*Gossypium*). The most important producers are the United States, the former Soviet Union, China, Pakistan, Brazil, Egypt, and India. *Gossypium barbadense* and *G. hirsutum* are preferred in the United States, while *G. herbaceum* is native to the Asian countries. The United States produce about one-third of the world's cottonseed oil (see also → Cellulose, Chap. 2.1.).

Table 25. Properties and analytical data of some vegetable butters

mp	ca. 0 °C
n_D^{40}	1.464 – 1.468

For fatty acid composition see Tables 1 and 2

The oil contains 0.4 – 0.6 % of malvalic acid, which presumably is the basis of the Halphen color reaction. The glycerides of cottonseed oil consist of approximately 12 – 14 % disaturated – monounsaturated, 52 – 58 % monosaturated – diunsaturated, and 25 – 30 % triunsaturated compounds.

Production. Egyptian cottonseed (not dehulled) contains 22 – 24 % oil, the American varieties on average 19.5 %. About 50 cottonseeds are contained in a pod, which opens when it is ripe. After removal of the cotton, the seeds are still covered with fine hairs (linters), which are removed with delintering machines that essentially consist of rotating sawtooth discs [81]. The seeds are then dehulled by passage through "dehullers" (essentially rotating knives) and screens – air classifiers. The dehulled seeds (30 – 40 % oil content) are expelled in continuous screw presses and the expeller residue is extracted with solvent.

Gossypol is present in the seed in concentrations of 0.4 – 2.0 %. However, only traces are detectable in the crude oil, because gossypol is partially deactivated (presumably by interaction with protein) during conditioning and expelling the seed. Crude cottonseed oil has a dark color because of dissolved resins and pigments, and must therefore be refined before further use. The crude oil is first clarified by settling or centrifuging and then neutralized with lye, mostly in continuous centrifuge lines. The neutralized oil is free of gossypol, light yellow, stable during storage, and is usually traded in this form. A very stable oil can be obtained by postneutralization, bleaching, and deodorization. Stearin separates out at temperatures between 0 and 8 °C. An oil with a low cloud point is obtained by removing these solid glycerides by cooling and filtration (winterization).

Use. Winterized cottonseed oil is a very stable salad oil. Cottonseed oil is also used in margarine blends without being winterized. Lard-like fats for use in margarine blends and shortenings are obtained by hydrogenation under iomerizing conditions. Such fats have a melting point between 30 and 35 °C and an iodine value of 60 – 80. Cottonseed oil hardened to a melting point of 36 – 37 °C is suitable as a couverture fat for confectionery products. The characteristic Halphen color reaction disappears on hydrogenating the oil.

13.2.3.2. Kapok and Related Oils

Kapok oil is derived from the fruit of a tree belonging to the Bombaceae family that grows in Indonesia, Sri Lanka, the Philippines, and South America.

The seeds in the fruit pods are covered with fine hairs (kapok), which are used in upholstering and contain ca. 25 % oil. Crude kapok oil, produced by preexpelling and solvent extraction, has a reddish-brown color and is similar to cottonseed oil in composition and further processing. It contains little or no gossypol. Kapok oil contains ca. 15 % of a C_{18} cyclopropenoic acid and therefore responds strongly to the Halphen reaction.

Okra oil is obtained from the seeds of *Hibiscus esculentis,* a family related to Gossypium and found in the United States and some Mediterranean countries. Kenafseed oil is contained in the seeds of *Hibiscus canabinus,* a plant native to India where it is grown for its fibers.

The properties of kapok, okra, and kenafseed oils are listed in Table 26.

13.2.3.3. Pumpkin Seed Oil

Pumpkin seed oil is popular as a high-quality, edible oil in Southeast Europe. It is obtained from carefully decorticated pumpkin seeds by grinding, conditioning the moistened ground seeds, expelling in hydraulic presses, and clarification by settling in special tanks, mostly on smaller locations. It has a reddish-brown color and a nutty taste. Refining yields an oil with properties similar to those of sunflower oil.

Saponifaction value	185 – 198
Iodine value	117 – 130
Nonsaponifiable matter	0.6 – 1.5 %
Solidification point	ca. −15 °C
n_D^{40}	1.466 – 1.469

For fatty acid composition see Tables 1 and 2

Melon seed oil is very similar in composition to pumpkin seed oil [82], the major fatty acids being palmitic (ca. 12 %), stearic (ca. 11 %), oleic (ca. 11 %), and linoleic (ca. 65 %).

13.2.3.4. Corn (Maize) Oil

Corn oil (maize oil) [*8001-30-7*] is obtained from the germ removed during the processing of corn (*Zea mays* L.) into starch.

Properties. Winterized corn oil becomes cloudy at about −10 °C.

Saponification value	187 – 196
Iodine value	109 – 133
Nonsaponifiable matter	1.3 – 2.0 %
n_D^{40}	1.465 – 1.466

For fatty acid composition see Tables 1 and 2

Corn oil glycerides consist of ca. 2 % disaturated – monounsaturated, 40 % monosaturated – diunsaturated, and 58 % triunsaturated compounds.

Production. Corn contains 3.5 – 5 % oil, about 80 % of which is in the germ and about 20 % in the endosperm. The corn germ itself contains about 36 % oil. The germs can be separated by wet or dry processing. Wet processing tends to be preferred because it gives a higher oil yield. The cleaned corn is first conditioned by soaking in warm water and is then milled and slurried with water. The germs are collected by flotation, washed, and dried. In dry processing, the ground corn is separated into germ and endosperm fractions by screening and air classification; suitable moistening and conditioning facilitate this fractionation. The oil is isolated from the germs by preexpelling followed by extraction with hexane.

The golden yellow, crude corn oil contains up to 3 % free fatty acids. After lye neutralization, bleaching, and deodorization it yields a light, highly stable oil. The content of tocopherols, predominantly γ-tocopherol, is nearly 1000 ppm. Salad oils that remain clear at refrigerator temperatures are obtained by winterization, during which about 500 ppm wax is removed.

Use. Corn oil is a universal oil; it is used especially as a salad oil and in salad dressings.

13.2.3.5. Cereal Oils

Oils are generally not extracted from cereal grains except rice and wheat. The cereal oils are, however, very important as constituents of bread, other bakery products, and animal feeds.

Wheat germ oil is extracted from the wheat germ (8 – 11 % oil) obtained as a byproduct of

Table 26. Properties of kapok, okra, and kenafseed oils

∗ Including 15 % malvalic acid.

milling wheat. It has a very high tocopherol content and is therefore popular as a dietetic oil.

Saponification value	180 – 189
Iodine value	115 – 126
Nonsaponifiable matter	3.5 – 6.0 %
mp	ca. 0 °C
n_D^{40}	1.468 – 1.478

For fatty acid composition see Tables 1 and 2

Rice bran oil [*68553-81-1*] is an important byproduct of rice processing. It is obtained by hexane extraction of the bran (brown outer coating) and the germ (8 – 16 % oil content) removed during grinding, dehulling, and polishing rice. The bran fraction must be extracted immediately, preferably after heat-sterilization, to destroy the very active lipases. Refined rice bran oil has a light yellow color and is a relatively stable edible oil. Rice bran oil hardened to 30 – 35 °C is often used in margarines and shortenings. In Japan and India ca. 100 000 t of rice bran oil are produced annually.

Saponification value	183 – 194
Iodine value	92 – 109
Nonsaponifiable matter	3.5 – 5.0 %
(including ca. 330 mg squalene per 100 g oil)	
mp	ca. −10 °C
n_D^{40}	1.466 – 1.469

For fatty acid composition see Tables 1 and 2

13.2.4. Oleic – Linoleic Acid Oils

This group encompasses a large number of drying and semidrying oils derived from plants growing in temperate and colder regions (see also → Drying Oils and Related Products). Some of these oils, such as hazelnut oil, poppyseed oil, walnut oil, and teaseed oil, only have regional significance, while sunflower oil, sesame oil, linseed oil, and safflower oil have considerable commercial importance.

13.2.4.1. Sunflower Oil

Sunflower oil [*8001-21-6*] is the seed oil of the sunflower, *Helianthus annuus,* that originated in America and is now grown extensively in East, West, and South Europe, the United States, Canada, South America, China, India, South Africa, and Australia. The annual plant reaches a height of 1 – 3 m, the short-stem varieties being preferred for ease of harvesting. The air-dry seeds contain about 45 % oil.

Properties. Sunflower oil begins to solidify at −16 °C; the cloud point is 0 – 5 °C.

Saponification value	188 – 194
Iodine value	125 – 144
Nonsaponifiable matter	0.4 – 1.4 %
n_D^{40}	1.466 – 1.468

For fatty acid composition see Tables 1 and 2

The linoleic acid content of sunflower oil is 50 – 70 % and tends to increase with decreasing temperatures during growing [83]. The glycerides contain 35 – 45 % diunsaturated and 56 – 63 % triunsaturated compounds. Linolenic acid is present to the extent of <0.4 %.

Production and Use. Sunflower oil is obtained by preexpelling followed by extraction of the expeller cake with hexane. Decortication is

practiced to a lesser degree; the hulls have to be burnt. The crude oil can be readily refined into a light, stable oil by lye neutralization, bleaching, and deodorization.

Cold-pressed sunflower oil is produced by expelling at $\leq 80\,°C$; posttreatment is limited to filtration and clarification. Such a "natural" oil is often recommended for dietetic purposes because of its relatively high concentration of phosphatides. Trace contaminants such as metals and pesticide residues, however, remain in the oil. Refined sunflower oil is used extensively in salad oils and margarine blends because of its oxidative stability. Winterization (removal of 500 – 2000 ppm of wax) of the deodorized or the neutralized and bleached oil at 10 – 15 °C yields an oil which does not cloud at refrigerator temperatures. Sunflower oil that is hydrogenated to a melting point of 32 – 35 °C (iodine value 70 – 75), under isomerizing conditions, is widely used in "one-oil" margarine blends.

Smaller quantities of a new sunflower variety are being grown in California; these plants yield an oil with an oleic acid content of about 80 % and hence a very high oxidative stability. This oil is recommended especially for salad and frying oils [84].

13.2.4.2. Sesame Oil

Sesame oil [*8008-74-0*] is contained in the seeds of *Sesamum indicum*, a plant resembling linseed and grown mainly in China, India, Africa, and Mexico. The flat seeds are 2 – 3 mm long and vary in color from white to brown-black; the oil content is 45 – 55 %. Harvesting is relatively difficult because of varying rates of ripening and the ripe seed pods shattering the seed. More uniform varieties with improved harvesting properties are being developed.

Properties. Sesame oil solidifies at −6 to −3 °C.

Saponification value	187 – 193
Iodine value	136 – 138
Nonsaponifiable matter	0.9 – 2.3 %
n_D^{40}	1.4665 – 1.4675

For fatty acid composition see Tables 1 and 2.

Crude sesame oil is yellowish and contains up to 3 % free fatty acids. The glycerides contain about 66 % dioleolinolein and oleodilinolein. Refined oil has a high stability due in part to the content of sesamol, a natural antioxidant formed by hydrolysis of sesamolin. The combined concentration of sesamol and sesamolin is 0.1 – 0.2 %. Sesamol gives a red color with an ethanolic solution of furfural in the presence of hydrochloric acid (color reaction of Baudouin and Villavechia); it also responds positively in color tests with an acidic solution of stannous chloride (Soltsien test), and with 3 % hydrogen peroxide – 75 % sulfuric acid (Kreis test).

Use. Sesame oil is widely used as an edible oil in the countries of origin. A small amount is exported for use in salad oils, salad dressings, and margarines. The addition of sesame oil to margarine is mandatory in some countries to provide a rapid means of identifying margarine by the above color reactions; for this application the oil may only be lightly bleached and deodorized at 150 °C.

13.2.4.3. Linseed Oil

Linseed oil [*8001-26-1*] is obtained from linseed or flax (*Linum usitatissimum*), which grows best in the temperate regions of Europe, Asia, and America. The flax fiber plant is a different variety of the same species. There is considerable variation in the iodine value of linseed oil from different regions. The iodine value of the oil tends to increase with severity of climate, but genetic and seasonal (e.g., rainfall) variations also have an influence [85]. While 180 – 185 is a typical iodine value range for individual lots, it may vary from 140 to 205.

The main producer countries are Canada, the United States, and Argentina. The brown, flat seeds contain ca. 40 % oil and 6 – 8 % water.

Properties. Fatty acid composition and other properties of linseed oil are given in Table 27 (see also Tables 1 and 2). Most applications require a linseed oil with a linolenic acid content of about 50 % and an iodine value of 170 – 190 [86], [87]. Linseed oil glycerides consist of about 5 % disaturated – monounsaturated, 43 % monosaturated – diunsaturated, and 52 % triunsaturated glycerides, which begin to solidify at

Table 27. Fatty acid composition and analytical data of vegetable oils of the oleic – linoleic group

−18 to −27 °C. Most of the glycerides contain an average of seven double bonds per molecule, which is the reason for the excellent drying properties of linseed oil (→ Drying Oils and Related Products). The use of linseed oil for edible purposes is limited to smaller quantities of cold-pressed oil (for dietetic purposes) and to hydrogenated linseed oil, which can be used in low concentrations in shortenings, and margarine blends.

Some wild linseed varieties (e.g., *Linum capitatum* and *L. flavum*) have linolenic acid contents as low as 11 %. Modern biotechnological techniques are being used in Australia and Canada in an attempt to transfer this property to *L. usitatissium*. An alternative approach is γ-ray induced mutation of *L. usitatissimum*.

Production. Linseed oil is obtained from the seed by preexpelling followed by hexane extraction of the press cake. After refining it is used predominantly in the technical sector for paints and coatings. A small amount is used in East European countries as edible oil. Linseed oil has a characteristic odor and flavor which cannot be removed entirely by refining. The crude oil is rich in phosphatides and gums which sediment on storage. The crude oil is often pre-deslimed by treatment with hot water followed by centrifugation. Oils virtually free of phosphatides and gums are made by post-desliming with sulfuric or phosphoric acid. Very light drying oils can be made by a further posttreatment consisting of lye neutralization and earth bleaching. To obtain virtually odorless oils, deodorization is required as a final step. Heating refined linseed oil to 260 – 285 °C increases its viscosity and gives a so-called "boiled" linseed oil, which is used in special paints and coatings.

13.2.4.4. Perilla Oil

The seeds of *Perilla ocymoides*, an Asian plant, yield perilla oil (30 – 50 %), which resembles linseed oil in appearance and application. For properties see Table 27. World production is about 25 000 t/a. Perilla oil is sometimes blended with linseed oil; in Asia it is also used as an edible oil .

Lallemantia oil (Asia) and Chia seed oil (Mexico) are further Labiatae seed oils with similar compositions.

13.2.4.5. Hempseed Oil

The seeds of hemp (*Cannabis sativa* L.) contain 30 – 35 % oil. Hempseed is grown in the Soviet Union, India, China, Japan, and Chile, and yields fibers in addition to the oil. Hashish can also be obtained from Indian hempseed varieties. Hempseed itself can be used as a foodstuff. The oil is normally produced by pressing the seed. For properties see Table 27. Hempseed oil has been largely replaced by linseed oil for technical purposes.

13.2.4.6. Teaseed Oil

Teaseed oils are obtained in China, Japan, India, and Turkey from the hazelnut-like seeds of

tea shrub varieties, which contain about 60 % oil. Tea shrubs grown for oil are generally not suited for tea-leaf harvesting. Teaseed oil is produced primarily from the seeds of *Thea sasanqua* n. (sasanqua oil) and *Thea japonica* n. (tsubaki oil) by drying, grinding, conditioning, and pressing or solvent extraction. After refining the oil is used for edible purposes, as a special lubricant, and for toiletries.

The principal acids of teaseed oils [88] are palmitic (ca. 16 %), oleic (ca. 60 %), and linoleic acid (ca. 22 %). Teaseed oils can be detected in concentrations above 10 % in olive oil by the Fitelson color reaction. The expeller cake and extraction meal cannot be used as such in animal feeds because of their high saponin contents. Total world production is ca. 30 000 t, half of which is exported.

13.2.4.7. Safflower and Niger Seed Oils

Safflower oil [*8001-23-8*] is the seed oil of the thistle-like safflower plant (*Carthamus tinctorius*), thriving in the West of the United States and in Mexico, North Africa, and India. The plant can be grown under fairly arid conditions, the oil yield increasing with available moisture in the soil. The seeds resemble small sunflowerseed kernels and can be harvested mechanically. The oil content of the seed is 25 – 37 %.

Saponification value	180 – 194
Iodine value	136 – 152
Nonsaponifiable matter	0.3 – 2.0 %
Solidification point	−13 to −25 °C
n_D^{40}	1.467 – 1.469

The fatty acid composition is similar to that of sunflower oil (see Tables 1 and 2).

Production. Modern processing involves grinding the seed followed by conditioning, expelling, and hexane extraction of the expeller cake.

Use. Safflower oil has a high oxidative stability and is being used increasingly in salad oils and dietetic margarines because of its high content of linoleic acid. Some years ago special varieties with oleic and linoleic acid contents of 80 % and 15 % respectively ("high oleic" varieties) were developed and recommended as especially stable frying oils. World production amounts to about 200 000 t/a.

Niger seed oil, closely resembling safflower oil in its composition, is derived from the seed of the gingli plant, which is grown fairly extensively in Ethiopia, Togo, and India.

13.2.4.8. Grape-Seed Oil

Grape-seed oil [*60-33-3*] is a valuable oil obtained from the grapeseed left in winery pomace [89]. The oil content averages 15 % (dry weight basis).

Properties. The flavor of grape-seed oil resembles that of olive oil; however, its fatty acid composition is similar to that of sunflower oil (see Tables 1, 2).

Saponification value	180 – 196
Iodine value	124 – 143
Nonsaponifiable matter	0.3 – 1.6 %
Solidification point	−10 to −20 °C
n_D^{40}	1.464 – 1.471

Use. After suitable refining (removal of chlorophyll can be difficult), grape-seed oil keeps relatively well and is used as a salad and cooking oil and in special margarine blends. In France and Italy, 5000 t and 20 000 t, respectively, of grape-seed oil are produced annually. It has been estimated that the world production of grape seed is 1.4×10^6 t, with a potential oil yield of about 190 000 t [82].

13.2.4.9. Poppyseed Oil

Poppyseed oil is obtained from the seeds of different varieties of *Papaver somniferum*. The oil content of air-dry seeds is 44 – 50 %. Cold-pressed oil is suitable for edible purposes, as is preexpelled and extracted oil after refining. Poppyseed oil is also used in smaller quantities for superior oil paints. The major fatty acids are stearic (ca. 10 %), oleic (ca. 16 %), and linoleic acid (70 – 75 %).

Saponification value	ca. 193
Iodine value	ca. 140
n_D^{40}	ca. 1.468

The world production of poppy seed amounts to about 25 000 t/a.

13.2.5. Leguminous Oils

The commercially most important representatives of this group are peanut oil and soybean oil. Soybean oil [*8001-22-7*] holds first place in the worldwide production of vegetable oils.

13.2.5.1. Soybean Oil

The cultivation of the soybean (*Glycine maxima*) in the United States and South America has steadily increased. The soybean has been known in China for 5000 years. Main producing countries today are the United States, Brazil, and Argentina. Cultivation in the temperate regions of Europe is possible but the hectare returns are generally not sufficiently attractive. New, higher-yielding varieties are constantly being developed; in the United States they thrive best in the "corn-belt," i.e., Illinois, Minnesota, Iowa, Indiana, Ohio, and Missouri.

The soy pods contain up to four soybeans (5 – 10 mm in length). The oil content varies between 17 and 22 % and the protein content reaches 40 – 45 % in dry matter. Climatic conditions have a considerable influence on the oil and protein content; late sowing and a cool, wet climate tend to lower the oil content and to increase the protein content. Development of low linolenic soybeans in the United States has been hindered by lower seed productivity.

Properties. Refined soybean oil has a light yellow color and a bland flavor.

Saponification value	188 – 195
Iodine value	120 – 136
Nonsaponifiable matter	0.5 – 1.5 %
Solidification point	−15 to −8 °C
n_D^{40}	1.465 – 1.469

For fatty acid composition see Tables 1 and2.

The oil contains 40 – 60 % triunsaturated, 30 – 35 % diunsaturated, and up to 5 % monounsaturated glycerides. In spite of the high tocopherol content (up to 1200 ppm) the stability of the refined oil is limited, primarily because of the content of linolenic acid. Autoxidation leads to "green", "seedy" off-flavors. Soybean oil can be detected in other oils by its fatty acid, tocopherol, and sterol contents.

Production. Soybeans are normally cracked and flaked prior to extraction with hexane. Preexpelling is not normally performed. Soybean meal is a valuable animal feed. Crude soybean oil contains 0.5 – 1.0 % free fatty acids as well as up to 2.5 % phosphatides, which are removed by hydration with 2 – 3 % water at 70 – 80 °C followed by centrifuging. Drying of the resulting lecithin sludge yields lecithin. Soybean oil is often postdegummed with phosphoric or citric acid prior to neutralization with lye, earth bleaching, and deodorization.

The yield of lecithin can be increased by steam-heating the flakes prior to extraction [39]. With the aid of special degumming techniques [44], the phosphorus content of the crude oil can be reduced to 20 ppm, which facilitates subsequent physical refining (i.e., direct treatment with acids and earth followed by combined stripping of free fatty acids and deodorization).

Use. Soybean oil is used in almost all fatty products, from salad oils to margarines. Hydrogenation with fresh catalyst at ca. 100 °C yields a liquid oil with significantly improved stability due to hydrogenation of linolenic acid. Hydrogenation under isomerizing conditions to melting points ranging from 36 to 43 °C yields products for use in shortenings and margarines. Liquid soybean oil is a so-called semidrying oil; it is used in combination with tung oil and as a component of alkyd resins for coatings.

13.2.5.2. Peanut Oil

Peanut oil (groundnut oil) [*8002-03-7*] is obtained from the seed kernels of the peanut plant (*Arachis hypogaea*), native to South America. The peanut is now being grown in China, India, South Africa, West Africa, Argentina, and

the United States. Senegal and Nigeria are the main African export countries. The annual plant thrives best on light, sandy soils and reaches maturity in 4 – 5 months. Peanuts for further processing are mostly shipped after shelling, whereas peanuts for direct consumption are normally exported in the pods. Peanuts are often designated according to their shipping ports, e.g., Bombay, Casamance, Rufisque, Bissao nuts.

Properties. The iodine value of peanut oil is 84 – 105; Rufisque oil has an iodine value of 84 – 90 and Argentinian oil a value of 100 – 105 in line with the higher content of linoleic acid. The saponification value is 185 – 196, n_D^{40} 1.461 – 1.465. Tocopherols and other antioxidants as well as hydrocarbons and sterols are found in the nonsaponifiable matter (0.5 – 1.0 %). The oil solidifies below 0 °C. For fatty acid composition see Tables 1 and 2. The oil contains 36 – 46 % triunsaturated, 47 – 52 % diunsaturated, and 7 – 11 % monounsaturated glycerides.

Production. The peanut pods contain up to four hazelnut-sized kernels which are covered with a thin, reddish-brown skin and contain 5 – 12 % water, 45 – 50 % oil, and 23 – 35 % protein. The pods are first removed by passage through cracking rolls or disk mills and over screens. This step also loosens the skins, which are removed by aspiration. The kernels are then screened, cracked, and expelled in screw presses. The residual oil in the expelled cake is extracted with hexane. Crude peanut oil contains low concentrations of phosphatides and up to 1.5 % free fatty acids. Lye neutralization, earth bleaching, and deodorization yield a light, slightly yellowish oil with a very good oxidative and flavor stability. Peanut kernels to be processed into oil and meal can contain up to 0.5 ppm of aflatoxins. The bulk of the aflatoxins remain in the meal where they can be deactivated by treatment with, for example, ammonia; traces of aflatoxin that might enter the oil are removed during neutralization with lye.

Use. Peanut oil is used as a superior salad and cooking oil, less so in margarines. In shortenings it is used as such or after hardening (*mp* 31 – 38 °C). On cooling to 6 – 8 °C, peanut oil becomes cloudy due to the crystallization of glycerides containing $C_{20} - C_{24}$ fatty acid groups. The glycerides can be removed by filtration but only with a low yield of clarified oil.

Peanut butter is made by grinding specially roasted peanuts and homogenizing the mash with addition of liquid and possibly also hydrogenated peanut oil.

13.2.5.3. Lupine Oil

Lupins are attracting attention worldwide as an arable crop for possible use in foods and feeds. *Lupinus albus, L. angustifolius, L. luteus,* and *L. mutabilis* are potential sources of edible oil. Whereas the first three species (sweet varieties) contain only 4 – 9 % oil in the dried seed, the seed oil content of *L. mutabilis* approaches that of soybeans. The main fatty acid components are palmitic (7 – 13 %), stearic (2 – 7 %), oleic (27 –53 %), linoleic (18 – 47 %), linolenic (2 – 9 %); lower concentrations of $C_{20} - C_{22}$ fatty acids are found [90]. The meal of *L. mutabilis* (bitter lupins) cannot be used as an animal feed without prior extraction of the alkaloids.

13.2.6. Cruciferous Oils

The seed oils of the traditional cruciferous plants are mainly characterized by their content of glucosinolates (sulfur-containing glycosides) and erucic acid. Rapeseed oil is the most important cruciferous oil.

13.2.6.1. Rapeseed Oil [91]

Rapeseed oil [*8002-13-9*] is the seed oil of different varieties of *Brassica napus* and *B. campestris*. The air-dry seed contains about 40 % oil and 7 – 9 % water. The production of rapeseed, one of the oldest oil crops known, has increased dramatically over the past 10 years. The introduction of so-called single-zero rapeseed varieties, i.e., varieties with an erucic acid content of less than 5 % of the total fatty acids, has made rapeseed oil universally applicable as an edible oil. Generally, it can be used to replace soybean oil. Whereas single-zero, spring-sown rapeseed varieties are grown in Canada, the EEC countries (with the exception of Denmark)

generally prefer winterhardy single-zero varieties because of the higher crop yields. Within the European Community the traditional rapeseed varieties with up to 50 % erucic acid in the oil are now Within the European Community only single-zero varieties are eligible for subsidy, and the United States has recently permitted the use of rapeseed oil with max. 2 % erucic acid. Whereas single-zero, spring-sown rapeseed varieties are grown in Canada, the EEC countries (with the exception of Denmark) generally prefer winterhardy single-zero varieties because of the higher crop yielused only for technical and specialty purposes.

The increase in planted acreage has led to greater availability and to processing throughout the year; a significant improvement of the quality of the meal and the oil has been achieved [92]. Canada, the European Community, Poland, Sweden, China, India, and Pakistan are the main producing countries. To facilitate the marketability of meal, double-low varieties, i.e., low in erucic acid and glucosinolates, are grown in Canada (spring-type) and are being introduced in the EEC (winter-type). The winter-sown varieties are larger in size and generally easier to process than the smaller spring-sown varieties.

Properties [92]. For fatty acid compositions see Tables 1 and 2. Analytical data such as iodine value and saponification value are functions of the erucic acid content. The high level of erucic acid in traditional rapeseed oil has been associated with irreversible organ changes in animal tests [92].

Production. Modern rapeseed processing entails flaking and cooking the seed prior to preexpelling in continuous screw presses; the press cake is extracted with hexane. Crude rapeseed oil contains up to 2 % free fatty acids and ca. 2.5 % phosphatides; it is degummed with water or acids, lye-neutralized, bleached with earth, and deodorized, analogously to soybean oil. The stability is also comparable. The phosphatide content of the crude oil can be reduced to 0.1 % (i.e., 20 ppm phosphorus) by special degumming techniques [44], which enable physical refining to be carried out.

The enzymatic degradation products of sulfur-containing glycosides (glucosinolates) in rapeseed can influence the taste of the crude oil and impair the nutritional properties of the meal [92]. The enzyme responsible for glucosinolate degradation, myrosinase, is destroyed by adequate cooking of the seed prior to expelling. Sulfur compounds are removed from the oil during refining; residual traces can affect the course of hardening since they act as catalyst poisons. The residual sulfur compounds in the extracted meal can be deactivated by treatment with alkali and heating.

Use. Traditional rapeseed oil containing up to 50 % erucic acid can be hardened into steep-melting products, *mp* 32 – 34 °C, suitable as partial coconut oil substitutes in shortenings and couvertures. Modern single-zero varieties are used as such, after mild hardening (which eliminates the linolenic acid), and after hardening under isomerizing conditions to raise the melting point to 30 – 43 °C. The reduced complexity in fatty acid composition of the hardened oil leads to a different crystallization behavior, which can be overcome by interesterification. Treatment of rapeseed oil with sulfur or sulfur compounds is the basis of mastic production.

13.2.6.2. Mustard Seed Oil

Mustard seed oil [*8007-40-7*] is derived from the seeds of black mustard (*Brassica nigra* or *Sinapis nigra*), brown mustard (*Brassica juncea*), and white mustard (*Brassica alba* or *Sinapis alba*). The seeds contain 30–35 % oil and high levels of glucosinolates. The erucic acid content of the oil is 40 – 50 %; it is therefore of interest primarily for technical applications.

13.2.7. Conjugated Acid Oils

13.2.7.1. Tung Oil and Related Oils

Tung oil [*8001-20-5*] is obtained from the kernels (oil content about 50 %) of the fruit of the tung tree, *Aleuritis fordii* (Chinese tung oil) or *Aleuritis cordata,* syn. *vernica* and *verrucosa* (Japanese tung oil). The oil from *Aleuritis montana* is almost identical in composition. Oils similar to Chinese tung oil are obtained from the nuts of *Aleuritis trisperma* (kekuna oil) and *A. moluccana* or *A. triloba* (lumbang oil). Tung trees

are cultivated in Southern China, Southern Russia, the Southern United States, and Argentina. Tung oil contains about 80 % α-eleostearic, 4 % linoleic, 3 % linolenic, 8 % oleic, 1 % stearic, and 4 % palmitic acid. For properties, production, and use, see → Drying Oils and Related Products.

13.2.7.2. Oiticica Oil and Related Oils

Oiticica oil [*8016-35-1*] is obtained mainly from the nuts of the Brazilian oiticica tree, *Licania rigida*. This evergreen tree reaches a height of 20 m and produces 150 – 900 kg of nuts per year. The kernels contain 55 – 63 % oil, which is generally obtained by pressing. Fresh oiticica oil is yellowish and of lardlike appearance. Oiticica oil for export is heated for 30 min at 210 – 220 °C, after which it remains liquid. Licanic acid, 4-oxo-9,11,13-octadecatrienoic acid, is the principal fatty acid. The oil yields varnishes similar to those made from tung oil (→ Drying Oils and Related Products).

Boleko or isano oil (ongoke oil) is obtained from the nuts of *Ongokea gore* ENGLER, a tree growing in the Congo regions. It contains isanic and isanolic acids, which are fatty acids with conjugated triple bonds.

Parinarium oils are contained in the kernels of various tropical trees of the family Rosaceae and have little commercial significance. *Parinarium laurinum*, a tree growing in Japan and Oceania, yields a seed oil which contains parinaric acid, an acid with 4 conjugated double bonds.

Néou oil, obtained from *P. macrophyllum*, contains about 30 % eleostearic acid. Eleostearic acid, in addition to licanic acid, has been found in po-yoak oil (obtained from *P. sherbroense*).

13.2.8. Substituted Fatty Acid Oils

13.2.8.1. Castor Oil

The seeds of the castor tree, *Ricinus communis*, contain 45 – 50 % castor oil [*8001-79-4*]. The evergreen castor tree belongs to the family Euphorbiaceae and grows in tropical and subtropical countries. It can reach a height of 10 m.

Properties. The fatty acids of castor oil consist of 87 – 91 % ricinoleic acid, 2 % stearic and palmitic acid, 4 – 5 % oleic acid, 4 – 5 % linoleic acid, and 1 % dihydroxystearic acid. Pure castor oil can be readily identified by its hydroxyl value, viscosity, and specific gravity. The oil is soluble in ethanol at room temperature and in boiling hexane.

d_{25}^{25}	0.945 – 0.965
n_D^{40}	1.466 – 1.473
Solidification point	−12 to −18 °C
Viscosity at 20 °C	935 – 1033 mPa s
$[\alpha]_D$	+7.5 to +9.7 °
Saponification value	177 – 187
Iodine value (Wijs)	82 – 90
Hydroxyl value	161 – 169
Acetyl value	144 – 150
Nonsaponifiable matter	0.2 – 0.3 %

Production. Cold pressing of the spotted, oblong seeds yields a light, viscous oil which is used primarily in pharmaceutical products. Subsequent expelling at elevated temperatures and extraction with hexane yields a yellowish-brown oil which is used primarily in technical applications. The extracted meal contains ricin, a toxic protein, and hence cannot be used as an animal feed.

Use. A drying oil can be made by dehydrating castor oil (dehydrated castor oil, → Drying Oils and Related Products, Chap. 4.). Pyrolytic cleavage at 300 °C gives undecylenic acid and heptaldehyde, raw materials for polymers and perfumes. Alkali fusion of castor oil yields 2-octanol and sebacic acid.

Hydrogenation yields a fat with a melting point of 84 – 86 °C and waxlike properties, finding application as a special lubricant. Air-blown castor oil is used as plasticizer for varnishes and polymers. The oil is also used in the production of transparent soap, textile processing aids, special lubricants, and toiletries.

13.2.8.2. Chaulmoogra, Hydnocarpus, and Gorli Oils

The seed kernels of *Taractogenos kurzii*, a tree native to Southeast Asia, contain 48 – 55 %

Table 28. Properties of some "leprosy oils"

chaulmoogra oil, the chief fatty acid components of which are chaulmoogric acid, hydnocarpic acid, gorlic acid, and lower homologues of hydnocarpic, palmitic, and oleic acid. Chaulmoogra oil and related oils such as hydnocarpus oils, obtained from Southeast Asian *Hydnocarpus* varieties, and the African gorli oil have been used in the treatment of leprosy; for properties see Table 28.

13.2.8.3. Vernonia Oil [93]

The seeds of *Vernonia anthelmintica* (of the Compositae family) contain an oil with a high percentage of vernolic acid (*cis*-12,13-epoxy-*cis*-9-octadecenoic acid). This epoxy acid is used in protective coatings, plastics, and other industrial products. Efforts have been made to grow *Vernonia* varieties as new industrial crops in the United States and Asia.

14. Individual Animal Fats

Animal fats are obtained from the milk or the fatty tissue of certain groups of animals (see also → Milk and Dairy Products). The content of depot fat varies from 0 to 60 %. The concentration and composition of the fat depend on type of animal, age, sex, and diet.

14.1. Land-Animal Fats [94]

14.1.1. Lard

Lard [*61789-99-9*] is the fat rendered from fresh, clean, sound fatty tissues from pigs in good health at the time of slaughter. The tissues do not include bones, ears and tails, internal organs, windpipes, or large blood vessels. Rendered pork fat is obtained from the tissues and bones of pigs in good health at the time of slaughter; it may contain fat from bones, skin, ears and tails, and other tissues fit for human consumption. A range of different quality grades is available.

Properties. European lard (iodine value ca. 60) is often harder than America lard (iodine value ca. 70).

mp	30 – 40 °C
Solidification point	22 – 32 °C
Saponification value	193 – 202
Nonsaponifiable matter	0.1 – 1.0 %

Lard consists of 4 – 8 % trisaturated, 32 – 40 % disaturated – monounsaturated, 45 – 50 % monosaturated – diunsaturated, and 3 – 10 % triunsaturated triglycerides. The main fatty acid components are shown in Tables 1 and 2. Lard contains low concentrations of arachidonic acid (0.4 – 0.9 %), trans fatty acids, as well as traces of branched and odd-numbered fatty acids such as saturated C_{15}, C_{17}, and C_{19} fatty acids and monounsaturated C_{17} and C_{19} fatty acids. Triunsaturated C_{18}, C_{20}, and C_{22} fatty acids are

also present. These typical fatty acids, together with the cholesterol that occurs in relatively high concentrations in animal fats, are the basis for detecting lard and other animal fats in vegetable oils and fats.

Production. Lard is obtained by dry or wet rendering. The best quality lard (acid value <0.8; moisture <0.1 %) is made from selected tissue which has been washed and cooled immediately after slaughter. After comminution, the fatty tissue is wet-rendered by steam heating at 50 – 60 °C (for continuous wet-rendering plants see Section 5.2). Prime steam lard and leaf lard are obtained similarly from nonselected or partially selected tissue. Packer's lard retains a typical flavor; refiner's lard has to be refined. Inferior varieties, made in part from inedible offal, include so-called white, yellow, and brown greases, which are used primarily in technical applications.

Lard can be fractionated into a higher- and lower-melting fraction. In order to prevent the use of inferior raw materials, some European countries do not permit the refining of lard. The addition of antioxidants significantly improves the organoleptic and oxidative stability. Lard can be refined either by neutralization with lye, followed by bleaching with ca. 1 % earth and deodorization at 180 – 240 °C, or by simple pretreatment with phosphoric acid – bleaching earth and subsequent distillative stripping. Interesterification improves the performance of lard as a shortening in terms of creaming and cakemaking [95].

Use. Lard is used extensively as an edible fat (shortening, margarines) and as an energy source in animal feeds.

14.1.2. Beef Tallow

Properties. The main fatty acids of beef tallow [*61789-97-7*] are shown in Tables 1 and 2. In addition, it contains up to 4 % of characteristic branched and odd-numbered fatty acids. These, together with cholesterol, identify tallow in vegetable oils and fats. Tallow also contains 6 – 10 % of trans fatty acids, resulting from bacterial hydrogenation in the rumen. Top-grade tallow is white to greyish-white; in summer it is slightly yellow because of carotenes taken up with fresh roughage. Table 29 shows analytical data for various beef tallow products. Beef tallow contains 14 – 26 % trisaturated, 22 – 34 % disaturated – monounsaturated, and 40 – 64 % monosaturated – diunsaturated glycerides.

The stability of beef tallow and its products is relatively poor in the absence of an added antioxidant. Primary quality criteria are odor and taste, concentration of free fatty acids, and absence of impurities and of refined low-quality tallow (white grease).

Production. The choice of fatty tissue determines the quality of beef tallow. Fat rendered from the carcasses of cattle is generally not quite as hard as that obtained from sheep and goats. The softest, most unsaturated fat is found under the skin, and the firmer fat is located near the middle of the animal. The consistency of individual lots of tallow is therefore influenced by the procedure used in trimming the carcass prior to fat rendering.

Edible tallow (dripping, max. 1 % ffa) is obtained from clean, sound, fatty tissues of beef cattle in good health at the time of slaughter. Premier jus (max. 0.5 % ffa) is obtained by rendering the fresh fat (killing fat) of heart, caul, kidney, and mesentery, excluding cutting fats at low temperature (50 – 60 °C). Tallow to be incorporated into margarine blends must be refined. Fractionation at 26 °C yields a lower-melting fraction (olein) and a higher-melting fraction (stearin). Tallow olein is an important component of some margarines and shortenings. Stearin is used in shortenings and in specialty margarines. Bone grease is obtained by expelling and extracting of comminuted bones ; it is used primarily in the technical sector and for animal feeds. Neatsfoot oil [*8037-20-5*] is a low-melting, inedible fat rendered from the feet of cattle; it is used as a special lubricant and leather dressing aid.

Use. Only a small part of the annually produced beef tallow is used as edible fat. The concentration in margarine is limited because of its poor stability but it is used more widely in shortenings. The technical grades are important raw materials for soap and fatty acid derivatives and for use in animal feeds. Specifications for tech-

nical tallows used for soapmaking are shown in Table 30.

14.1.3. Mutton Tallow

Mutton tallow finds applications primarily in the technical sector. Superior grades are similar to corresponding beef tallows.

Saponification value	192 – 198
Iodine value	31 – 47
Nonsaponifiable matter	0.1 – 0.6 %
Density (40 °C)	0.896 – 0.898 g/cm^3
n_D^{40}	1.455 – 1.458
mp	44 – 55 °C

The main fatty acids are palmitic, stearic, and oleic acids (Tables 1 and 2). Up to 4 % of branched and odd-numbered fatty acids and traces of trans fatty acids are also present.

14.1.4. Horse, Goose, and Chicken Fat

Horse fat is softer than lard or rendered pork fat. The fatty acid composition (Tables 1, 2) is strongly influenced by diet. Branched and odd-numbered fatty acids occur up to about 2 %. The nonsaponifiable matter is <0.5 %, the melting point 29 – 40 °C. Horse fat is occasionally used in meat and sausage products in some countries.

Goose fat has a relatively low melting point, 25 – 35 °C; its consistency is often improved by addition of lard.

Chicken fat is also low-melting, *mp* 23 – 40 °C. The fatty acid composition (see Tables 1 and 2) is strongly influenced by diet.

Table 32. World production of oil fruits, oilseeds, oils, and fats according to countries (annual average, expressed as oil/fat in 1000 t)

14.2. Marine Oils [96]

Marine oils are the oils obtained from whales and fish. Fish oils have a high content of highly unsaturated (4 – 6 double bonds) C_{20}, C_{22}, and C_{24} fatty acids (cf. Tables 1 and 2). The oils from freshwater fish contain less C_{20} and C_{22} fatty acids and more oleic and linoleic acid than those from sea fish. These differences are caused primarily by differences in the composition of the feed. Only oils obtained from sea fish are commercially important.

14.2.1. Whale Oil

The whale population has been depleted to such an extent that whale oil is now completely overshadowed in commercial importance by the various fish oils. The Antarctic has long been the catching area. Whales are processed in modern factory ships (see also Section 5.3). The color of the oil can be very light, and the concentration of free fatty acids very low. Since 1913, when it was discovered that the oil can be converted into a stable edible fat by hydrogenation, many thousands of tons of hardened whale oil have been produced for margarine, cooking fats, and soapmaking.

Saponification value	185 – 205
Iodine value	110 – 135
Nonsaponifiable matter	<2 %
Slip point	22 °C
n_D^{65}	1.4554 – 1.4579

Whale oil has been graded according to free fatty acid content and color (apart from moisture and dirt):

Grade 0: pale yellow, max. 0.5 % ffa
Grade 1: pale yellow, max. 2.0 % ffa
Grade 2: amber yellow, max. 6.0 % ffa
Grade 3: pale brown, max. 15.0 % ffa

Grade 0 – 2 whale oils are hydrogenated for edible purposes. Prior to hydrogenation the oil

[g] $\sum$ Fish oil, whale oil, and sperm oil.

is lye-neutralized and bleached. Whale oil can be hydrogenated into soft and hard fats. Soft fats with a melting point between 33 and 38 °C are produced by hydrogenation under isomerizing conditions with a partially inactivated nickel catalyst. Fats with a melting point between 40 and 45 °C are produced with relatively fresh catalyst. The crude hydrogenated fats are filtered to remove catalyst, treated with weak lye, bleached, and deodorized. In some cases, post-treatment can be restricted to treatment with citric acid – bleaching earth followed by distillative stripping. Hydrogenated whale oil is stable for about 6 months. The softer fats are used primarily for shortenings, the higher melting ones for preserves, dry soups, and special margarines.

The main components of sperm oil [*8002-24-2*] are esters of fatty acids and fatty alcohols (waxes). Sperm oil is a valuable raw material for high-quality cosmetic preparations. It is being replaced by jojoba oil, a seed oil from a shrub (*Simmondsia chinensis*) indigenous to the Sonoran desert and being cultivated in arid zones around the world. Its seeds contain 50 – 60 % of a liquid wax composed of esters of fatty acids and fatty alcohols [97].

14.2.2. Fish Oil [98]

The bulk of fish oils is produced in modern plants by cooking comminuted fish or fish offal, expelling in screw presses, and centrifugation; or by extraction of dried fish meal with hexane (see Section 5.3). Refining and hydrogenation yields fats of edible quality which are used in margarine and shortening blends. For historical reasons fish oils are not permitted as edible oils in the United States. The main crude oil origins are Japanese (iodine value ca. 180), U.S. (menhaden: iodine value 150 – 160), South American (iodine value

ca. 200), and Scandinavian (iodine value 130–140).

The oil content of fish is subject to seasonal variations and generally lies between 8 and 20 %. Typical properties of various fish oils are shown in Table 31 (for fatty acid composition see Tables 1 and 2). All fish oils contain small concentrations of branched and odd-numbered fatty acids.

Use. Fish oils are processed into hydrogenated fats analogously to whale oil [100]. However, due to their content of polyunsaturated fatty acids and sulfur compounds, hydrogenation requires more hydrogen and more catalyst. The melting points of hardened fish oils range from 31 to 45 °C. Organoleptic stability generally improves with decreasing iodine value of the starting oil and with increasing melting point of the hardened product. Hardened fish oils are used in shortenings and margarine blends. They have good creaming and cake-making properties but do not perform as well in frying.

Much of the oil of cod, halibut, and shark is stored in the liver. Cod-liver oil and halibut-liver oil are valued for pharmaceutical purposes because of their high content of vitamin A (1500–50 000 i.u./g) and vitamin D (40–200 i.u./g). Typical properties of cod-liver oil are as follows:

Saturated fatty acids, %	
C_{14}	6
C_{16}	6
C_{18}	8
Unsaturated fatty acids, %

1. Introduction

Originally the term “fatty acids” was applied only to carboxylic acids separated from animal and vegetable fats. Today it includes all saturated and unsaturated aliphatic carboxylic acids with carbon chain lengths in the range of C_6 – C_{24}. Fatty acids obtained by splitting natural fats and oils are quantitatively far more important than synthetic fatty acids. Different processes for modification of natural fatty acids have been developed and are used to achieve special properties in the different fields of application. The principle production flow sheet in the oleochemistry chain is shown in Figure 1 [1].

Figure 1. Oleochemical processes and products

The world production of oils and fats has grown from 60 × 10^6 t in 1980 to 124 × 10^6 t in 2003. Vegetable oils rose to a share of about 80 %, whereas animal fats decreased to 20 %. The majority of natural oils and fats is used for human nutrition (ca. 80 %) and animal feed (ca. 6 %). The remainder of ca. 14 % or 17 × 10^6 t is consumed by the chemical industry [2-5].

For technical applications, fatty acids play an important role since many years. World production capacity of fatty acids in 2000, not including tall oil fatty acids, was about 5.4×10^6 t and is estimated to grow to ca. $6.5 \times 10^6 – 8.1 \times 10^6$ t in 2005/2006. Expansion mainly took place and is planned in the Asian region. Based on the data for 2000 the contribution of Asia was about 50 %, Europe 30 %, and America 20 % [6], [7].

Although many fatty acids — often with unusual structures — occur naturally, with few exceptions (see Dimerization) only the straight-chain $C_6 – C_{22}$ carboxylic acids are of commercial importance. Moreover, in many fields of application, more or less broad cuts are employed, rather than chemically pure individual fatty acids.

2. Properties

2.1. Physical Properties

The face of chemical manufacturing is changing rapidly, shaped by such powerful forces as intensified global competition, increased stringency of safety and environmental regulations, and increased customer demand for consistent attainment of high product quality. In this context computer-aided process engineering (CAPE) plays a dominant role in the fast development of new or in revamping of existing processes. All process simulators use properties as intermediate variables. Their values are obtained from experiments or property models chosen to mimic the behavior of the process components and the operating conditions. For the process engineer, thermodynamic data form an essential basis for process development, design, and optimization. The thermodynamic data include thermal, transport, and caloric properties of components, such as density, heat capacity, and especially phase-equilibrium properties such as vapor – liquid phase equilibria. These data are necessary for the simulation of heat and mass transfer, design of thermal separation processes, and chemical reactors [8-10].

Especially important are physical data associated with a phase change from the solid to the liquid state or vice versa. The behavior on melting is highly specific for each fatty acid. For this reason, determination of the melting point is often used for identification and quality control. The melting point of a fatty acid depends on the number of carbon atoms, the degree of saturation, and the structure of the hydrocarbon chain.

With straight-chain fatty acids, the melting point increases alternatingly with increasing chain length, so that the melting points of fatty acids with an odd number of carbon atoms are somewhat lower than those of the adjacent even-numbered fatty acids. The behavior of fatty acids with chain lengths $C_6 – C_{22}$ is illustrated in Figure 2.

Figure 2. Melting point alternation of straight-chain saturated fatty acids

For unsaturated fatty acids, the relationship is more complex. In general, a decrease in the melting point is observed with increasing number of double bonds. However, naturally occurring *cis* isomers melt or solidify at lower temperatures than the corresponding *trans* isomers, as shown in Figure 3 for the C_{18} fatty acids. Other interesting parameters are the position of the double bond and, for polyunsaturated acids, the location of double bonds relative to each other. Fatty acids in which a conjugated arrangement (—CH ═CH —CH ═CH —) occurs have considerably higher melting points than nonconjugated acids. An example is given for eleostearic acid (Fig. 3).

Figure 3. Effects of number of double bonds, cis – trans isomerism, and conjugation on melting points of C_{18} acids

A comprehensive survey of physical and chemical properties of straight-chain fatty acids is presented in Tables 1 and 2 [11-32].

The behavior of fatty acid mixtures is characterized by a considerable lowering of the individual melting or solidification points. Most binary mixtures have phase diagrams with a eutectic point. Depending on the types of acids combined, three groups can be distinguished: mixtures of saturated fatty acids, mixtures of saturated and unsaturated fatty acids, and mixtures of unsaturated fatty acids. In Figures 4 and 5, typical solidification and melting point curves are illustrated. The values are plotted as a function of the concentration of the higher melting component [28], [33-35].

Figure 4. Freezing points of binary systems of saturated C_8 – C_{22} fatty acids

Figure 5. Freezing or melting points of binary systems of unsaturated fatty acids

The *liquid densities* of fatty acids are shown in Figure 6. The densities of C_6 – C_{20} fatty acids are all less than 1000 kg/m^3. The lower the molecular mass and the higher the degree of unsaturation of fatty acids, the higher is their density.

Figure 6. Densities of liquid straight-chain fatty acids as a function of temperature

Optical properties such as light refraction have long been used to identify liquids and establish their purity. The refractive index of pure fatty acids increases with increasing molecular mass, number of double bonds, and conjugation [30]. However, today measurement of the refractive index of fatty acids plays only a minor role in quality control. Modern gas chromatographs are the standard equipment for the determination of mixture compositions.

The *heat of fusion* is the energy consumption for phase transition from the solid crystal to the liquid state. Measured values of molar heat of fusion for straight-chain saturated fatty acids are listed in Table 1. Heats of fusion increase alternatingly with the length of the carbon chain. Fatty acids with an even number of carbon atoms have a higher heat of fusion than adjacent odd-numbered acids. Above a chain length of ten carbon atoms the heat of fusion can be determined by the following equations:

for even-numbered fatty acids (Table 1):

$$\Delta H_f = 4.2928 \cdot n - 14.99$$

for odd-numbered fatty acids (Table 1):

$$\Delta H_f = 4.152 \cdot n - 20.134$$

where ΔH_f is the heat of fusion (kJ/mol), and *n* the number of carbon atoms.

Table 3 lists heats of fusion for some C_{18} unsaturated fatty acids. They were derived from experimental data or calculated with the aid of theoretical relationships [28], [29], [36]. As expected, the values are lower than those for saturated fatty acids.

Table 3. Heat of fusion of some unsaturated C_{18} fatty acids

Component	Heat of fusion, kJ/mol
Oleic (9 c)	30.14
Elaidic (9 t)	38.94
Linoleic (9 c, 12 c)	51.50
Linolenic (9 c, 12 c, 15c)	39.36
α-Eleostearic (9 c, 11 t, 13 t)	43.96
β-Eleostearic (9 t, 11 t, 13 t)	55.27

The heat of vaporization and the related properties boiling point and vapor pressure are very important for the design and optimization of distillation columns by using simulation tools.

The *boiling point* and the molar latent heat of vaporization rise with increasing molecular mass (see Tables 1 and 2). The influence of the degree of saturation is of minor importance. As expected, fatty acids show an almost ideal equilibrium behavior, that means, fulfillment of Dalton's and Raoult's laws (especially under vacuum).

The *molar latent heat of vaporization* can be estimated by use of the integrated form of the Clausius – Clapeyron equation:

$$\Delta h_v = \frac{R T_1 T_2 \ln\left(\frac{p_1}{p_2}\right)}{T_1 - T_2}$$

where Δh_v is the molar latent heat of vaporization (J/kmol), R the universal gas constant (8314 J $kmol^{-1} \cdot K^{1}$), T_1, T_2 are temperatures (K), and p_1, p_2 pressures (Pa).

The vapor pressure curves for fatty acids of chain lengths C_6 to C_{20} are presented in Figure 7 [18], [22], [23].

Figure 7. Vapour pressure of straight chain saturated fatty acids as a function of temperature

The following correlation relates vapor pressure and temperature of saturated, straight-chain fatty acids:

$$t = \frac{\sqrt{M} + 0.06075 \log^2 p + 1.30 \log p - 7.63}{\left(-3.54 \cdot 10^{-4} \log^2 p\right)\left(-3.91 \cdot 10^{-3} \log p\right) + 0.05191}$$

where t is the temperature (°C), p the vapor pressure (mbar), and M the molecular mass (kg/kmol).

The *heat of combustion* is of great practical and theoretical importance. It can be used to calculate the *heat of formation*, by means of which the enthalpy change in chemical reactions can be established. Heat of combustion and heat of formation increase with increasing number of carbon atoms. The data for unsaturated fatty acids, as far as they are known, are almost identical with those for the corresponding saturated fatty acids. For straight-chain saturated fatty acids the following linear correlations can be used (Tables 4 and 5):

$$-\Delta H_{comb} = 655.06 \cdot n - 447.71$$
$$\Delta H_{form} = 33.42 \cdot n + 368.33$$

where n is the number of carbon atoms (C_6 – C_{20}), ΔH_{comb} the heat of combustion (kJ/mol), and ΔH_{form} the heat of formation, kJ/mol

For straight-chain saturated fatty acids in the liquid phase, the *molar heat capacity* is shown in Figure 8. For solid fatty acids, the values are presented in Figure 9 [19]. The molar heat capacity is particularly important when considering heat-transfer problems (e.g., design of heat exchangers).

Figure 8. Molar heat capacity of straight-chain saturated fatty acids (liquid phase)

Figure 9. Molar heat capacity of straight-chain saturated fatty acids (solid phase)

Thermal conductivity and dynamic viscosity are important properties in the assessment of heat transfer and fluid dynamics. The thermal conductivity and dynamic viscosity of straight-chain saturated fatty acids as a function of temperature are shown in Figures 10 and 11, respectively.

Figure 10. Thermal conductivity of straight-chain saturated fatty acids

Figure 11. Dynamic viscosity of straight-chain saturated fatty acids as a function of temperature

At temperatures up to 100 °C, fatty acids and water have only low *mutual solubilities*, and the solubility of fatty acids in water is considerably lower than that of water in fatty acids. Both solubilities increase with increasing temperature and decrease with increasing chain length. Some data on the mutual solubilities of the binary water – saturated fatty acid system are given in Table 6. At high temperature and pressure, however, the solubility of water in fatty acids and in fatty acid – fat mixtures is considerable. At 250 °C and 5 MPa, for example, approximately 12 % of water dissolves in the fatty acid phase of a mixture of tallow fatty acids and water, while the value is 24 % for a mixture of coconut fatty acids. Complete miscibility with water is obtained at 320 and 290°C, respectively [37]. This fact must be considered in the high-pressure splitting of fats and oils (see Section Hydrolysis — Industrial Procedure).

Above their melting points, fatty acids are miscible in all proportions with many organic solvents such as hydrocarbons, ketones, esters, alcohols, and chlorinated or aromatic solvents. In the solid state, the solubility of saturated fatty acids depends on chain length and increases with increasing temperature. Unsaturated fatty acids, however, are completely miscible at room temperature and display only limited solubility at lower temperature [28], [33], [38], [39].

In Tables 7 and 8, the solubilities of saturated and unsaturated fatty acids in methanol are given as examples.

The *surface tension* at the liquid – vapor interface and the interfacial tension in liquid – liquid systems are important properties for estimating the wetting behavior at solid surfaces and the coalescence behavior in liquid – liquid extraction. The surface tension of liquid fatty acids decreases with decreasing chain length and with increasing temperature. In Figure 12 and Table 9, some data are presented or listed for saturated fatty acids.

*System: Fatty acid - water

Dry fatty acids are poor conductors of electricity. The *specific electrical conductivity* is a function of chain length and temperature. Values vary from 0.6×10^{-9} to $83 \times 10^{-9}\ \Omega^{-1}\ m^{-1}$. The *relative dielectric constants* vary between 2 and 3, depending on the number of double bonds and the temperature [29].

The *flash point* and the *autoignition temperatures* of fatty acids are listed in Table 10 [41]. They rise significantly with increasing chain length.

Table 10. Average values for flash points and autoignition temperature of saturated and unsaturated fatty acids

2.2. Chemical Properties

Fatty acids undergo the typical reactions of the carboxyl group (⟶ Carboxylic Acids, Aliphatic). Commercially important derivatives such as esters, amides, nitriles, and alkali or other metal salts are obtained by conventional methods (see also Uses). Hydrogenation of the carboxyl group to form fatty alcohols usually involves esterification and is discussed in detail under ⟶ Fatty Alcohols.

Unsaturated fatty acids are sensitive to atmospheric oxygen (see Storage and Transportation).

For industrially important reactions involving the double bond of unsaturated fatty acids (e.g., hardening, *cis – trans* isomerization, and dimerization) see Modification of Fatty Acids. Scientific approaches for the functionalization of fatty acids have been reviewed [42], [43]. Focus here is on the reaction of the double bonds of the fatty acids in order to achieve other or special properties.

[Top of Page]

3. Production of Natural Fatty Acids

3.1. Resources and Raw Materials

Fatty acids are widely distributed in nature as components of lipids such as oils and fats (esters of fatty acids with glycerol), waxes (esters of fatty acids with fatty alcohols), sterol esters, and other minor compounds.

Vegetable oils are obtained mainly from seeds and only to a small extent from fruit pulp; animal fats are obtained from fat deposits and from organs (⟶ Fats and Fatty Oils). Oils and fats are one of the most important renewable resources suitable to develop sustainable concepts. The term fats normally means materials of solid consistency, whereas liquid materials are referred to as oils. The definitions are indistinct, since the solid – liquid state of fats depends on temperature and many fats show a semisolid consistency at ambient temperature.

For the manufacturing of fatty acids on a commercial scale, only oils and fats which are regularly available in large quantities are used as raw materials. Much research in plant breeding has been done in the last few decades to adjust the fatty acid composition of vegetable oils to the needs of the food industry. The main commercial results were achieved with low erucic acid rapeseed oil (LEAR, Canola) and high oleic sunflower oil (HOSO) [44], [45]. By the use of transgenic approaches the fatty acid profile of soybean and rapeseed oil has been modified [46]. Though these developments have not been commercially used until now, they show that in future fatty acid compositions of vegetable oils may vary over broader ranges.

Fats and oils have characteristic fatty acid profiles [47], [48]. Tables 11 and 12 list the fatty acid composition of important fats and oils for fatty acid production.

Table 11. Fatty acid composition of important oils and fats (weight percent)* [continued in Tab. 12

Soap-stock fatty acids are byproducts in the processing of crude fats for human nutrition. The pulping of wood in the sulfate pulp process results in the digestion of the lipids composed of esters of triterpene alcohols that are present in the resin. The free fatty acids found as constituents of tall oil (⟶ Drying Oils and Related Products) represent another starting material for the commercial production of fatty acids.

Natural waxes, such as sperm oil or jojoba oil, are not significant sources of fatty acids.

3.2. Fat Splitting

Fats are fatty acid esters of glycerol and are also known as triglycerides. By splitting the glycerides, fatty acids and glycerol can be recovered (Fig. 13).

Figure 13. Formation and splitting of glycerides

The most important splitting agents are water (hydrolysis), methanol (methanolysis), caustic soda (saponification), and amines (aminolysis) (Fig. 14). Because of drawbacks in the subsequent purification of glycerol, saponification and aminolysis are of less commercial interest when full recovery of glycerol is important. Today, most soaps and fatty acid amides are manufactured via fatty acids or fatty acid methyl esters. Exceptions are ricinoleic acid and hydroxystearic acid, which are produced commercially by saponification of castor oil and hardened castor oil, respectively. In this way, the esterification reactions that occur with the hydroxyl groups of ricinoleic and hydroxystearic acids during hydrolysis are avoided.

Figure 14. Agents used to split triglycerides

3.2.1. *Hydrolysis — Principles*

The reactants in the hydrolysis of fats form a heterogeneous system made up of two liquid phases. The disperse aqueous phase consists of water and glycerol; the homogeneous lipid phase contains glycerides and fatty acids. The hydrolysis of fat to form glycerol and fatty acids occurs essentially as a homogeneous reaction by dissolved water in the lipid phase. The water – fat interfacial reaction is of minor significance [49]. The reaction takes place in several stages, via partial glycerides (diglycerides and monoglycerides), as shown in Figure 15.

Figure 15. Typical course of hydrolysis reaction at 235 °C and 3.5 MPa using 1 part oil and 2 parts water

The total reaction can be summarized as follows (cf. Fig. 13):

$$\text{Triglyceride} + 3\,\text{Water} \rightleftharpoons 3\,\text{Fatty acid} + \text{Glycerol}$$

The reaction proceeds to a state of equilibrium. At higher temperature, the endothermic nature of fat hydrolysis results in displacement of the equilibrium in favor of the split products. The rate at which equilibrium is reached corresponds approximately to a first-order reaction [50]:

$$\frac{dc}{dt} = k \cdot c$$

where

k = rate constant
t = reaction time
c = concentration of triglyceride

However, at the beginning and the end, the reaction does not proceed according to this equation. This is because the necessary excess of water is present only after an induction period. Toward the end of the reaction, the glycerol concentration (which is not considered in the equation) has an increasing influence because of the reverse reaction.

Values of the rate constant k are highly dependent on temperature because of the increased solubility of water in the lipid phase [49], which leads to:

$$k = k_0 \cdot e^{-E/RT}$$

where

k_0 = statistical probability of reaction
E = energy of activation
T = absolute temperature
R = universal gas constant

An increase in temperature of 10 °C, for example, approximately doubles the value of k. Catalysts influence the rate constant k by changing the energy of activation, whereas k_0 is affected only slightly by temperature.

In the liquid two-phase system prevailing during hydrolysis of fats, the concentrations of the reactants depend primarily on the diffusion between the lipid and aqueous phases. Mass transfer can be influenced favorably by large, turbulent interfaces. During the entire reaction two mass transfer effects, which proceed in opposite directions, are of special importance for a high degree of conversion: (1) diffusion of water into the lipid phase and (2) removal of glycerol from the lipid phase into the aqueous phase by water extraction.

The overall hydrolysis reaction is a very slow process mainly controlled by temperature and duration. In comparison, mass transfer of glycerol and water across the phases is relatively fast [51]. LASCARAY [50]. summarized the complex reaction conditions in an empirical formula. He described the degree of splitting (hydrolysis) in the lipid phase as a function of the glycerol concentration in the aqueous phase:

$$H = 100 - 0.8 \cdot c_G$$
$$(c_G \text{ in the range from } 0 \text{ to } 20\ \%)$$

where

H = degree of splitting (% ffa = acid value/saponification. value × 100%)
c_G = glycerol concentration (wt % in the water phase)

Optimization of this process by chemical engineering largely determines the yields of fatty acid and glycerol. Temperature, duration, heat transfer, and hydrodynamic conditions, as well as the choice of catalyst, are the important parameters for approaching near-equilibrium conditions under the most favorable economic conditions, i.e., in the shortest time possible.

3.2.2. *Hydrolysis — Industrial Procedure*

Pretreatment. Crude commercial fats are sometimes purified to remove troublesome impurities, such as minerals, gums, soaps, and proteins, before they are subjected to splitting and following steps such as distillation or crystallization. The normal procedure is to heat the crude fat and then filter it or treat it with a small quantity of 0.3 – 1.0 % sulfuric acid. Animal fats from slaughterhouses contain varying amounts of dissolved packaging materials that consist mainly of polyhydrocarbons with differing rheological properties. These can best be separated from fats by filtration or centrifugation at ca. 70 °C with the use of filter aids. Also, settling of the fats over several days before splitting can be helpful for removing most of the impurities, which form deposits at the bottom of the tank. In this connection, one of the indicators for the quality of the fats and later yield of fatty acids is the share of total fatty material, which is defined as 100–M.I.U. (% moisture + % insolubles (dirt) + % unsaponifiables, e.g., polyethylene). Typical values for traded animal fats are a saponifiability of 97 % (0.5 % moisture, 0.5 %

dirt, 2 % unsaponifiables).

To suppress oxidation, degassing to remove atmospheric oxygen is recommended. All hydrolytic processes employ demineralized water as the splitting agent. The hardness of water reduces catalyst efficiency and increases the salt content of the glycerol obtained.

Catalysts. Up to 100 °C, fat hydrolysis is very slow. For palm oil with an initial content of 5 % free fatty acids (ffa), a degree of splitting of ca. 20 % is reached after 10 d at 100 °C [52]. TWITCHELL achieved a technical breakthrough in 1898 with an effective catalyst consisting of aromatic hydrocarbons, oleic acid, and concentrated sulfuric acid (Twitchell reagent). The original Twitchell batch process operates under atmospheric pressure at almost 100 °C in wooden tubs. The batch time is 12 – 24 h, and the degree of splitting without a change of water is about 80 – 85 % [53].

Lipases are specific biocatalysts for ester hydrolysis and exhibit optimum efficiency at temperature below 50 °C. Enzymatic splitting of fats is therefore of great interest today as a low-energy process combined with the advantage of low thermal stress to the heat-sensitive fats. Furthermore, enzymatic splitting can be applied to special fats which can be normally hydrolized only by saponification and neutralization (see Enzymatic Hydrolysis Processes). An improved fat-splitting process using lipase presplitting prior to pressure splitting is described by Henkel Corporation [54]. The partial hydrolysis achieved by the presplitting step mainly eliminates the induction period encountered during pressure splitting and leads to time savings or higher capacity of about 20 % compared to similar nonpresplit fats.

Acid catalysts are generally very effective for accelerating hydrolysis reactions. At higher temperature, however, material corrosion occurs. This problem does not arise when basic oxides are used as catalysts. Dibasic metal oxides have a higher activity than the more strongly alkaline monobasic metal oxides. In the literature, zinc oxide in its active form as zinc soap is described as the most effective accelerator for hydrolysis. The Zn^{2+} ion functions not so much as a Lewis acid, but rather as a phase-transfer catalyst which carries water in the form of hydrate into the lipid phase [55], [56].

Temperature. Without catalysts, the rate of fat hydrolysis is economical only above 210 °C (Table 13). The development of high-pressure techniques was the decisive step in making hydrolysis of fats a large-scale manufacturing process. Initially, batch operation in autoclaves at medium pressures of 0.6 – 1.2 MPa was employed.

Table 13. Influence of temperature on splitting time [57], [58]

t, °C	Time to reach equilibrium, min *		
	Beef tallow	Coconut oil	Peanut oil
225	156 (62)	158 (58)	156 (50)
240	82 (34)	85 (33)	85 (25)
260	47 (18)	46 (23)	53 (16)
280	34 (8)	33 (10)	33 (10)

* In parentheses: halftime of splitting.

Modern continuous splitting units operate at 210 – 260 °C and 1.9 – 6.0 MPa. The rate of splitting in high-pressure plants is sufficiently fast without any catalysts. With rising temperature and pressure, the mutual solubility of the two phases increases to a point where a homogeneous phase is formed. When coconut fat is used, this occurs at 293 °C and 8.0 MPa. For tallow, the values are 321 °C and 12.0 MPa [59].

Equipment. High pressure splitting can be carried out in autoclaves, which are employed mainly in batch operation. With a battery of autoclaves in parallel, a one-stage process can be carried out in cycles (Fig. 16). Autoclaves in series enable multistage processes to be operated batchwise or continuously with co- or countercurrent streams [60].

Figure 16. Batch fat splitting in two parallel autoclaves with direct heating

a) Splitting autoclaves; b) Flash tank; c) Separation tank; d) Condenser

For high throughput rates, spray columns operating countercurrently are used [60], [61-63]. The main feature of this system is the countercurrent movement of the two liquid phases as a result of their difference in density. Efficient mutual extraction is essential for fast hydrolysis of fat. This process, first described by H. MILLS [59], has been modified by several companies. Commercial countercurrent splitting towers with varying features (e.g., internal heat transfer between lipid and aqueous phases for energy conservation) were designed years ago, for example, by Colgate-Emery [64], Foster-Wheeler, Feld & Hahn [60], Crown Iron Works [65] (formerly Wurster & Sanger) and Lurgi [66]. An overview on plant and equipment suppliers is given in [67]. Based on the Crown Iron Works process [65] the main elements are shown in Figure 17.

Figure 17. Continuous fat splitting (Foster – Wheeler)

a) Splitting column (250 – 260 °C, 5 – 6 MPa); b) Flash tank; c) Level control; d) Pressure control; e) Condenser

Fat and process water (mainly condensate from the concentration of glycerol water) are pumped into a splitting column by high-pressure metering pumps. Fat is fed in near the bottom of the column ca. 0.5 m below the interface; water is fed in at the top. The reaction zone, which lies between the upper and lower heat-exchange zones, is heated to 250 °C by direct feeding of high-pressure steam. The upper heat-exchange zone (water – fatty acid) is provided with baffles, whereas the lower heat-exchange zone (oil – glycerol/water) includes the interphase. In case of difficult fats (emulsion formation), feeding of the fat above the interface is recommended. A pressure regulator controls the discharge of fatty acids at the top, and an interface regulator automatically adjusts the flow of the glycerol-water mixture (12 – 18 % glycerol) from the bottom of the column.

Mass transfer between the lipid and aqueous phases, as described by LASCARAY [50], has a decisive influence on the final degree of fat splitting. Degrees of splitting >98 % are achieved today by applying principles of liquid – liquid extraction, especially at the top of the splitting tower (water against fatty acid).

Steam from expansion of the glycerol – water can be used as an energy source for the following evaporation of the glycerol – water, which comes out of the splitter with 15 – 20 % glycerol and which is generally concentrated to 88 % crude glycerol.

Continuous splitters have a consumption of high-pressure steam of about 200 kg steam per tonne of oil or lower. The ratio of the feeding rates of oil to water is normally about 2:1. In addition, the condensate of the direct-heating steam must be added to the water phase. The oil feeding rate per unit splitter volume (empty column) can be specified at about 200 kg h^{-1} m^{-3}, which corresponds to a residence time of the lipid phase of about 4 h.

Within the normal working range, the splitting degree (see Hydrolysis — Principles) shows a nearly linear dependence on the input flow rate of the oils. For the same column at constant splitting temperature, the plots for different oils and fats have different positions (see Figure 18). The splitting degree decreases with increasing input rate.

Figure 18. Splitting degrees of continuous splitting columns. Typical dependence from input rate.

The hydrolysis of fatty acid methyl esters into fatty acids and methanol is of special interest for generating short-chain fatty acids ($C_6 – C_{10}$) if the demand is higher than normally generated via oil splitting and fatty acid fractionation. The equipment and the conditions of normal direct steam splitting are not applicable. Therefore, formerly two-step processes were used, such as saponification and subsequent neutralization or transesterification with glycerol (glycerinolysis) and then normal splitting. Both are not very economical. Recent developments describe more efficient ways by direct splitting with the help of organic catalysts such as sulfonic acids [68] or metal soaps of organic acids [69]. The last process has been successfully used for some years on a industrial scale. Furthermore, enzymatic splitting of fatty acid methyl esters has been developed and can be recommended as suitable process (see Enzymatic Hydrolysis Processes).

3.2.3. *Enzymatic Hydrolysis Processes*

The high temperatures employed for steam splitting makes this process unsuitable for sensitive triglycerides, conjugated systems, hydroxylated fats and oils, and polyunsaturated oils with high iodine numbers (Table 14). There are also difficulties associated with alkaline hydrolysis, namely, high energy costs and the need to acidify the formed soaps in a second step to obtain the fatty acid products.

Table 14. Disadvantageous effects of chemical hydrolysis with sensitive triglycerides

Component	Disadvantage of chemical hydrolysis
Conjugated	thermal degradation, isomerization
Hydroxylated	dehydration, polymerization
Polyunsaturated	polymerization, coloration

A goal of technology in the 21st century is to become more environmentally friendly. For this reason, industrial enzyme catalysis technology based on green chemistry concepts is indispensable.

The enzymatic process is an alternative way to produce fatty acids, in which enzyme-catalyzed hydrolysis ⟶ Enzymes – Fat Splitting is carried out under milder conditions that restrict secondary reactions to a very low level; for example, coloration and the *trans* isomer content of the processed fatty acids are reduced due to the high enzyme selectivity.

Modification of starch and proteins by enzymatic processes is well established on an industrial scale. However, the use of enzymes to modify lipids, despite the significant research effort made in this field, is mostly still in the development stage.

The hydrolysis of oils and fats is catalyzed by lipase (EC 3.1.1.3), which breaks the ester bonds of acylglycerides. Lipases are produced by plants, animals, and microbes. However, plant and animal enzymes are not used commercially, while microbial enzymes (fungal, yeasts, molds and bacteria) are used extensively [70], [71].

Lipases have the particular characteristic of catalyzing the reaction only at the water/lipid interface. Thus, the surface area available for reaction is a crucial process efficiency factor, and an excess of water is essential. Both free enzymes in emulsion systems and immobilized enzymes have been extensively studied for performing the hydrolysis of fats and oils [72-77].

Lipases can be nonspecific enzymes that remove any fatty acid from the glycerol, e.g., lipases from *Candida cylindracea* [78]. Alternatively, they can be specific for positions in the triglyceride, e.g., 1,3-specific lipases from *Candida antarctica* preferentially release fatty acids from postions 1 and 3 of glycerol to give fatty acids and monoglycerides [79]. A lipase from *Geotrichum candidum* is specific for fatty acids with a *cis*-9 double bond [80].

Most microbial lipases for hydrolysis have a pH optimum of between 5 and 9 at the emulsion interface. The optimum temperature is 30 – 50 °C. Depending on enzyme concentration, stirring, water content, number of hydrolysis steps, and oil source, nearly complete hydrolysis can be performed in 8 – 72 h.

Prolonged reaction times can eventually yield complete hydrolysis of triacylglycerides to fatty acid and glycerol when a 1,3-specific lipase is used. To circumvent this issue, enzyme mixtures can be used in the process, as described in the enzymatic splitting process of castor oil to obtain high-quality ricinoleic acid [81]. The enzymatic hydrolysis can be conducted as a presplitting process that is combined with subsequent chemical hydrolysis to enhance the capacity of the overall fat splitting process [82].

As mentioned in Section Hydrolysis — Industrial Procedure methyl esters can be used instead of glycerides as further components to produce fatty acids. Most enzymes are inactivated in the presence of small amounts of methanol or they catalyze the esterification reaction to produce methyl esters. Therefore, the methanol content should be reduced by continuously removing methanol from the system, and water should be present in excess. There are two processes possible to obtain short-chain fatty acids in high quality: continuous removal of a methanol – water distillate and splitting and phase separation in several steps [83].

Lipase not only catalyzes the hydrolysis of glycerides, but can also catalyze the synthesis of esters or interesterification reactions by a reverse reaction (see Enzymatic Esterification and ⟶ Enzymes – Interesterification).

3.3. Separation of Fatty Acids

3.3.1. *Distillation*

Crude fatty acid mixtures from splitting contain a number of high-boiling impurities (e.g. partial glycerides, soaps, glycerol, sterols, phosphatides, pitch, color bodies) as well as low-boiling components (water, low molecular mass hydrocarbons, aldehydes, methyl ketones, odor bodies). These impurities must be removed by distillation to ensure the high quality of fatty acids demanded by customers. Processed crude fatty acids such as oleic acids obtained from crystallization (see Crystallization) and modified fatty acids (see Modification of Fatty Acids), as well as fatty acid bottom products of fractionation columns are also subjected to distillation.

On the other hand fatty acids are very reactive chemical components that can be damaged by oxidation, thermal decomposition, dehydration, polymerization, polycondensation, and other chemical reactions taking place in manufacturing plants. Typically, the reaction rate increases exponentially with increasing process temperature. The byproducts formed lead to a deterioration in color, color stability, odor, and other quality-control criteria. And from an economical point of view, byproducts lead to reduced product yields, which increase manufacturing costs.

Both mentioned points have a decisive influence on the engineering design of fatty acid manufacturing plants. The equipment development since ca. 1985 has concentrated on the chemical properties to produce fatty acids of high quality together with appropriate economic efficiency. The major requirement in the field of fatty acid distillation is to avoid product damage. This requires the liquid to be exposed to the lowest possible boiling temperature for the shortest period of time.

In the following two principle technologies for products of different quality and composition are considered in more detail: distillation and fractionation. Currently, both processes are only conducted continuously. Therefore, batch processes, which were often applied in the past, are not considered.

Due to their limited thermostability, fatty acids must be distilled or fractionated at low temperature under high vacuum. However, in conventional vacuum distillation systems the hydrostatic pressure of the liquid phase above the heating surfaces of the evaporator system partly destroys the effect of the vacuum system. As a solution, modern falling-film evaporators are widely used. Since ca. 1985 falling-film evaporators have practically replaced the forced-recirculation evaporators used until then. In most falling-film evaporators the heating medium is steam or heat-transfer fluids (e.g. Marlotherm, Dowtherm).

The falling-film evaporator is especially desirable from a product point of view, as it offers a short residence time. In falling-film evaporators, liquid and vapors flow downwards in parallel. The liquid to be partially evaporated is preheated to boiling temperature. An even thin film enters the heating tubes via a distribution device at the top of the evaporator, flows downward at boiling temperature, and is partially evaporated. This gravity-induced downward movement is increasingly augmented by the cocurrent vapor flow.

Falling-film evaporators can be operated with very low temperature differences between the heating media and the boiling liquid, and they also have very short product contact times, typically just a few seconds per pass. These characteristics make the falling-film evaporator particularly suitable for the partial evaporation of fatty acids as heat-sensitive products, and it is today the most frequently used type of evaporator in the field of fatty acid distillation. Falling-film evaporators must be designed very carefully for each operating condition; sufficient wetting of the heating surface by liquid is extremely important for trouble-free operation of the production plant. The proper design of the liquid-distribution system is critical to achieve full and even product wetting of the tubes. If the heating surfaces are not wetted sufficiently dry patches will occur; at worst, the heating tubes will be completely clogged. Thermal decomposition of fatty acids could occur.

Another advantage of falling-film evaporators is the low liquid holdup in this type of unit. As a result, the plant can be started up quickly.

The most important development in distillation and fractionation of fatty acid mixtures surely is the substitution of conventional trays and dumped packings by structured packings. The main advantage is that the pressure drop of a packed bed relative to the corresponding number of theoretical stages is much less than that of conventional trays. This pressure drop is less than 0.5 mbar per theoretical stage with a typical *F* factor of about 2 – 2.5 $Pa^{0.5}$. This is smaller by factor of 12 – 15 than that of conventional trays.

Another advantage of structured packing is the high separation efficiency. Typical established and experimentally investigated values for distillation of fatty acids in industrial plants are in the range 2 – 2.2 theoretical stages per meter packing (e.g., Mellapak 250, Sulzer AG) [84]). Latest developments in this field (Mellapak Plus, Sulzer AG; Montz-Pak Type M, Montz GmbH [85-88]) ensure higher *F* factors without simultaneous deterioration of the separation efficiency. This leads to distillation plants and fractionation columns that can be operated at lower pressure drop. The result is less thermal stress on the fatty acids. Therefore, the quantity of byproducts produced by thermal decomposition is reduced. This leads to better product quality and higher product yields.

Another benefit of structured packings is the extremely small liquid holdup in comparison to conventional trays. For this reason the residence time is lower than in the case of conventional trays. A typical holdup value of a structural packing is in the range of 2.5-3 % relative to the packing volume.

Additionally, structured packings permit a very wide range of liquid loads in the operating point of the production unit. For example, the minimum liquid load for Mellapak 250 (Sulzer AG) is in the range of 0.2 – 0.3 $m^3\ m^{-2}h^{-1}$, and the upper limit ranges up to 200 $m^3\ m^{-2}h^{-1}$.

Another gain of structured packings is the increased safety in scale-up in comparison to conventional trays. At present there is no longer need for experimental tests for the purpose of plant design. Modern flow-sheeting tools [89-91] guarantee a safe design.

To reduce the pressure drop in the distillation columns new types of condensers were developed and applied successfully in industrial practice. For example, special plate-type heat exchangers [92], [93] show extremely low pressure drop. This feature reduces the top pressure of a distillation plant and ensures the manufacture of high-quality fatty acids.

Distillation. Crude fatty acids from splitting contain a series of high-boiling impurities and lower boiling components. These impurities must be removed by distillation. In the following some industrial examples are presented and analyzed.

In a plant offered by Lurgi [94], the crude fatty acid is predried in the drier and degasser under vacuum (Fig. 19). It is then drawn into the distillation still, which is equipped with two sections of structured packing and internal chambers for separation of heavy ends. The chamber incorporates one or more heating elements and baffles. Propelling steam, which expands into a large volume in the vacuum space, circulates the liquid between heating elements and baffles by the principle of an air lift pump. The fatty acid is sprayed into a fine maze as it impinges on the baffles and heavy ends evaporate on the large liquid surface. The nonvaporized portion accumulates at the bottom and is circulated again, while the remaining undistilled residue is continuously discharged. A falling-film evaporator is used to reduce thermal stress on the product. An optional heat-recovery system can be applied in the top condenser.

Figure 19. Fatty acid distillation plant (Lurgi AG)

At the top of the column fatty acid vapors are condensed in surface condensers. To remove low-volatility light-end components causing odor and color, the main distillate is taken out as a middle fraction, and the light ends as the top fraction. Heavy ends, primarily color carriers, can either be withdrawn separately or recycled directly for complete or partial redistillation.

The above-mentioned positive features of falling-film evaporators for the distillation of fatty acid mixtures are exploited in a manufacturing process of Cognis (Fig. 20). Crude fatty acid mixture is degassed and dried, preheated, and then evaporated in a falling-film evaporator. The vapors pass through the distillation column equipped with modern structured packings and condense stepwise in the upper part of the column in two condensers connected in series. The lower boiling components are removed from the second total condenser. The condensate from the first (partial) condenser is returned as undercooled reflux to the rectifying part of the distillation column. The main fraction is withdrawn above the stripping part of the distillation column. A second falling-film evaporator concentrates the residues in a side chamber of the still. With this arrangement, a strong fractionating effect is achieved, by which low-boiling odorous substances and high-boiling colored materials are removed.

Fractional Distillation. Fractional distillation is applied to obtain products of high purity. Typical raw materials are fatty acid mixtures with chain lengths of C_6 – C_{18} from the splitting of coconut or palm-kernel oil and unsaturated C_{18} – C_{22} fatty acids from the splitting of rapeseed oil. The purity required for the products

(referred to as fatty acid fractions in this section) is up to 99 %. Separation of fatty acids from resin acids in tall oil [95] is also accomplished by fractional distillation, while the fractionation of tallow, soybean, cottonseed, and linseed fatty acids is of lesser importance.

Separation usually takes place in vacuum distillation columns, column systems, or complex distillation arrangements with sophisticated internals (new generation of modern structured packings) to intensify mass and energy transport between the vapor and liquid phases and to minimize pressure drop in the columns. Before fractionation begins, the crude fatty acid must be degassed and dried. The final step is overhead distillation of the bottom product of the last column to improve the color.

In the bottom of the column, heat is supplied by means of falling-film evaporators. In the top of the column heat is removed by surface condensers. The vacuum system includes a multistage jet pump which permits a pressure of less than 2 – 3 mbar at the top of the column. Sealing the plant is particularly important because the presence of atmospheric oxygen results in rapid oxidation of fatty acids.

Column systems are being increasingly applied for the fractionation of fatty acid mixtures. The simplest case is a production plant with a system of several distillation columns connected in series (Fig. 21) [96]. The multicomponent mixture from splitting is first degassed and dried in a dryer. Then the mixture is fed to a system of distillation columns. Separation takes place in all columns in two product streams: top and bottom product streams.

Figure 21. Sequence of fatty acid fractionation columns (Sulzer AG)

Figure 22 illustrates an improved alternative for the separation of crude coconut or palm kernel fatty acid [97]. Here, three products are simultaneously manufactured in a distillation column with a sidestream. The precut (C_6 – C_{10}) forms the top product. The bottom product contains the C_{16} – C_{18} components. The fraction C_{12} – C_{14} is produced as a sidestream. This sidestream is separated in two further columns to produce the C_{12} products and C_{14} products. The precut is specially treated and is used in a column system for the production of C_6, C_8, and C_{10} fatty acid fractions. For the separation of the C_{16} – C_{18} bottom product of the first column a sidestream column can be used again to obtain, e.g., a 16/70 % fraction as top, 18/92-94 % as sidestream, and a bottom fraction of C_{18} and higher.

Figure 22. Fractionation of fatty acid mixture in a sequence of distillation columns with sidestreams

For all considered separation processes one distillation column can also be used several times, but this approach is not economical. The reason is repeated cooling and heating of the product streams, which raises energy costs and deteriorates the quality of the end products due to longer residence time. Furthermore, this technical solution demands many additional tanks for intermediate products.

A further application of a column with sidestream (Figure 23) permits production of the three products (C_{16} – C_{18}, C_{18} – C_{20}, and C_{22}) in one run [97]. The aim of the separation procedure is the production of erucic and behenic acid from the raw material after the splitting of erucic-rich rapeseed oil. In this case low top pressure, low pressure drop, and short residence time of the products in a distillation column due to the high temperature (ca. 270 °C) are important.

Figure 23. Manufacturing of erucic and behenic acids

The above-mentioned systems cover two or three product streams in distillation columns connected in series. Figure 24 shows two conventional arrangements for the separation of a typical four-component mixture (usually known as direct and indirect sequences). Process integration has proven to be very successful in reducing the energy costs for conventional distillation arrangements. One of the most significant nonconventional arrangements involves “thermal coupling”. Figure 25 shows a short survey of nonconventional arrangements which use thermal coupling. In thermal coupling part of the heat transfer necessary for separation is provided by direct contact via the product flows. Typically, the arrangement consists of a main distillation column surrounded by additional devices such as prefractionator, side stripper, and side rectifier.

Figure 24. Conventional structures for the separation of a ternary system

Figure 25. Complex distillation arrangements

The key advantage of the complex column over a sequence of simple columns is more compact equipment and substantial reduction of investment and manufacturing costs, instrumentation, man power, and maintenance. The application of these arrangements in industrial practice is changing rapidly because of recent advances in simulation, dynamics and control.

An interesting solution in the field of multicomponent distillation of oleochemical mixtures is a column with a vertical partition, proposed by Sulzer Chemtech for the separation of fatty acids [96]. This configuration is shown in Figure 26 and is often referred to as a dividing-wall column [98]. The advantage of this partitioned column is that a ternary mixture can be distilled into pure product streams with only one column, one reboiler, and one condenser. This reduces the cost of separation in comparison to sidestream columns or column systems [99-102]. It is expected that all above-mentioned complex arrangements will expand into the fractionation of fatty acid mixtures increasingly in the future because of clear economic advantages.

Figure 26. Dividing-wall column

Process Control. The increasing role of product quality control of distillation columns for manufacturing of fatty acids is significant. Driven not only by meeting fatty acid specifications and economic goals, distillation columns must also satisfy new customer demands. In many distillation columns product quality has been directly controlled by means of temperatures inside the column. However, since the feed to the distillation columns consists of multicomponent mixtures and they are often changed by operating conditions of the upstream units, rigid relations do not always exist between column temperatures and product qualities. In this context, it is difficult to control product quality by using column temperatures. In the modern oleochemical industry, there is a strong emphasis on the use of process analyzers to provide real-time process quality data for the purpose of maximum operating efficiency.

Fatty acids manufactured by using distillation columns with liquid or vapor sidestreams instead of two or more columns mostly require higher utility usage. Therefore, the application of these columns provides significant economic incentives of reduced capital and operating expenses. On the other hand, they also pose a more challenging control problem than standard distillation columns. Columns with a liquid or vapor sidestream have an additional degree of freedom and therefore an additional dimension of coupling. Therefore, these columns are generally more difficult to control than typical distillation units.

A newer process control concept for fatty acid qualities in distillation columns with a liquid sidestream has been presented [103]. The fatty acid composition is determined by an on-line gas chromatograph (Fig. 27). The determined product composition is then checked for consistency by an expert system embedded in the distributed control system (DCS). An additional supervision level is a fundamental element of the control system, implemented in the DCS and consisting of two basic parts: a diagnostic and an information level. The basic function guarantees an error-free operational sequence of the composition control by interception of all uncertain information due to the plant operator (errors in setpoints, product specifications) or the measurement procedure (errors of analyzing system). The next step of the control system covers composition control (Fig. 27). It was realized by using decentralized, time-discrete PI controllers [104]. A special user interface in the DCS for the plant operator was developed as a diagnosis, information and warning platform.

Figure 27. Process control system with on-line gas chromatograph

In summary, only the successful integration of all mentioned elements of the developed composition control system guarantees a stable operating point of the fatty acid fractionation plant.

3.3.2. *Crystallization*

Separation by crystallization means the separation of a fatty acid mixture into a higher melting fraction, consisting mainly of saturated acids, and a lower melting fraction, consisting mostly of unsaturated acids.

The prototype of this process is the separation of tallow fatty acids into stearic acid (stearin) and oleic acid (olein). The stearin obtained from this separation has an iodine value of less than 20 and is normally hardened subsequently to an iodine value of 1. The crude olein obtained has a cloud point below 3 °C. Apart from tallow fatty acid, distilled or crude fatty acids from the splitting of, bonefat, soybean, sunflower, palm, rapeseed oil or the C_{16} – C_{18} fraction of palm kernel fatty acid can be employed.

When molten fatty acids such as tallow fatty acid are cooled, the higher melting, saturated constituents crystallize first, while the appreciably lower melting, unsaturated constituents remain liquid over a defined temperature range. Because of the formation of mixed crystals, the solid phase still contains residual unsaturated fatty acids. Conversely, residual saturated fatty acids are found in the liquid phase because of their solubility in unsaturated fatty acids. Since various chain lengths and degrees of saturation are present in natural fatty acid mixtures, a theoretical discussion of this solid – liquid equilibrium is extremely difficult. From the experimentally determined phase diagram for tallow fatty acid, the composition and quantitative ratio of the two phases “stearin” and “olein” can be seen in relationship to temperature and to the composition of the starting material (Fig. 28).

Figure 28. Phase diagram of tallow fatty acids

A = saturated fatty acids; B = unsaturated fatty acids [105]

Olein must be removed at a temperature corresponding to the desired olein content. However, because the olein content of stearin increases with decreasing temperature, separation at higher temperature of a stearin with a low olein content may be advisable. Separation of the liquid phase can then be carried out in a second step at a lower temperature.

Fractional Crystallization without Additives. In the “panning and pressing process, ”the molten tallow fatty acid is cooled slowly to ambient temperature in flat aluminum pans. Fatty acid cakes are wrapped in cloths and separated from the liquid fraction in hydraulic presses. The liquid from the first pressing is cooled to 5 – 10 °C, and more stearin crystals are removed, which results in an olein with a cloud point of 5 – 10 °C. Today, the pressing process is no longer used because it is labor-intensive and separation is poor [31].

The fractional crystallization developed by Sulzer [106] is a solvent-free batch process divided into the three principal steps of 1) crystallization, 2) partial melting (sweating), and 3) melting. Depending on the purity of the final product the simpler process of static crystallization can be applied or, in the case of higher qualities, falling-film crystallization. The static crystallizer uses cooling plates immersed in a stagnant melt, whereas the falling-film crystallizer is equipped with a tube bundle that is cooled from outside, and the processed melt is pumped in a loop through the tubes. Both processes can be combined with each other or with other processes such as distillation. Typical applications are monomer purification and isomer separation to obtain purified products such as acrylic acid or paraffin waxes. In the case of fatty acids the static unit is used for enrichment of unsaturated acids based on rapeseed, soybean, or sunflower oil.

Fractional Crystallization with Addition of a Wetting Agent. Liquid and solid phases can be separated more easily and more completely if an aqueous solution of a wetting agent is added to the crystal paste. The stearin crystals are wetted by the wetting agent and form an aqueous suspension which is separated from the olein phase by centrifugation.

This principle was developed by Henkel as a continuous, two-stage hydrophilization process [107]. The mode of operation can be seen from the flow diagram (Fig. 29). Lurgi built in the past one- and two-stage plants based on this principle [108], [109].

Figure 29. Flow diagram of two-stage hydrophilization process

a) Stirred vessel (wetting); b) Centrifuge; c) Cooler; d) Heater; Settling tank (separation of wetting solution); f) Settling tank (washing stage)

Stearin crystals form when molten tallow fatty acid is cooled to ca. 20 °C. The aqueous wetting agent solution containing a hydrophilization component such as sodium lauryl sulfate and an electrolyte such as magnesium sulfate is added to the mixture of stearin crystals and liquid olein, and the crystals are thus wetted. The stearin – water suspension is separated from olein in a centrifuge. Olein from the first stage is cooled in a second step to the desired cloud point, treated again with a solution of wetting agent, and separated in a centrifuge. The cold stearin suspension from the first stage is heated to above the melting point of the stearic acid and separated from the wetting agent solution. Before additional processing (e.g., final hardening), the stearin is washed and dried under vacuum. The stearin suspension from the second stage is recycled by adding it to the starting material for the first stage. The solution of wetting agent and electrolyte is also recycled; only a small amount of fresh material must be added continuously to maintain optimal concentration. Cooling is normally carried out indirectly by passing chilled brine through the outer jacket of a scraped surface crystallizer. Otherwise, the mixture can be cooled by evaporating part of the water under vacuum.

The hydrophilization is sometimes referred to as the Henkel [31], the Lipofrac [110], or the Lanza (Unilever) [111] process.

Fractional Crystallization from Solvents. Another method of crystallization is based upon the fact that saturated fatty acids are less soluble than their unsaturated counterparts in organic solvents such as methanol, hexane, or acetone. The first process of this type was put into operation by Emery (Emersol plant, Fig. 30) [31], [112].

Figure 30. Flow diagram of Emersol® crystallization plant (Cognis Corporation)

(a)economizer (b)crystallizers (c)vacuum pump (d)vent scrubber (e)seal liquid receiver (f)filter (g)cake melt tank (h)wash chiller (i)wash receiver (j)filtrate economizer (k)filtrate receiver (l)wash economizer (m)wash alcohol receiver (n)process alcohol (o)oleic preheater (p)alcohol condenser (q)oleic evaporator (r) stearic surge tank (s)oleic surge tank (t)oleic still (u)oleic drier (v)preheater (w)stearic still (x)stearic drier

A ca. 30 % solution of, for example, tallow fatty acid in 90 – 95 % methanol is cooled continuously to –12 °C in a tubular crystallizer equipped with scrapers. Optionally, a crystal promoter or modifier may be added to the process to improve the separation efficiency [113]. From the resulting crystal paste, the mother liquor containing mainly unsaturated fatty acids is sucked through a rotating vacuum filter. The filter cake, which contains saturated fatty acids, is washed free of the mother liquor and melted. The solvent is recovered from both the filter cake and the mother liquor by distillation. The stearin obtained still contains ca. 5 – 15 % oleic acid and has an iodine value of ca. 5 – 15. Depending on the filtration temperature, the olein has a cloud point from 1 to 8 °C [114].

The corresponding Armour process applies acetone as a solvent [115], [116]. Indirect cooling can be replaced by direct cooling, e.g., by partial evaporation of the solvent at reduced pressure [117], [118].

The Bernardini [119] and Rau [120] processes also operate on the principle of fractional crystallization from solvents.

Common to all these processes is the need for extensive safety measures (explosion prevention) and for environmental protection with respect to the emission of solvents. Recovery of solvents requires additional equipment and energy.

Adductive Crystallization with Urea. Adductive crystallization with urea, that is, formation of urea inclusion compounds, is a well-known technique for fractionation of fatty acids. The method is useful to separate saturated fatty acids from unsaturated and to isolate selectively a variety of polyunsaturated fatty acids (PUFAs) from lipid mixtures, e.g., to increase the nutritional quality of the fatty acids.

For example 97 – 99 % oleic acid containing only 0.2 % polyunsaturated material has been obtained from olive oil fatty acid [121]. The fatty acids in soybean, fish, wheat germ, and grape-seed oils have also been separated by this method [122].

The main selectivities of this procedure are [123]:

- Enhanced selectivity against inclusion with increasing number of double bonds per fatty acid molecule
- Preferences for fatty acids of longer chain length
- Preference for *trans* versus *cis* double bonds in inclusion
- Sensitivity for double bond position

Processes for fatty acid fractionation [123], [124-127] are listed in Table 15.

Table 15. Fractionation of fatty acids by formation of urea inclusion compounds

Fatty acid source	Application
Fish oil	isolation of EPA* and DHA*
Linseed oil	isolation of ALA*
Rapeseed oil	removal of saturated fatty acid
Borage oil	isolation of GLA*
CLA reaction mixture	isolation of 18:2 (9c, 11 t) and 18:2 (10t, 12c)

*EPA: eicosapentenioc acid; DHA: docosahexenoic acid; ALA: α-linolenic acid; GLA: γ-linolenic acid CLA: conjugated linoleic acid.

The formation of urea inclusion compounds is an exothermic and equilibrium reaction. The equilibrium and stability constants of urea complexes for different fatty acids are listed in Table 16 [128].

Table 16. Equilibrium and stability constants of urea complexes for different fatty acids

Component	Equilibrium constant *K*	Stability constant 1/*K*
Caprylic acid	0.07	14
Caprinic acid	0.0185	54
Lauric acid	0.0063	159
Myristic acid	0.0029	345
Palmitic acid	0.0017	588
Stearic acid	0.0002	5000
Oleic acid	0.0024	476
Linoleic acid	0.019	53

The differences in the constants show that fractionation is possible under certain conditions.

A scheme of a urea complexation and crystallization process for separating saturated from unsaturated fatty acids is demonstrated in Figure 31.

Figure 31. Process scheme for separation of saturated and unsaturated fatty acids with urea complexation [128]

Other Separation Methods.
Adsorption. For the separation of oleic and linoleic acids, UOP recommends an acid-resistant, hydrophobic, non-zeolite molecular sieve (Silicalite) [129]. Oleic acid is first selectively adsorbed and later displaced with the aid of a solvent. A nonionic, hydrophobic, spatially cross-linked styrene polymer has been used for the same purpose [130].

Extraction. Laboratory separation of stearic and oleic acids has been achieved by high-pressure extraction with a supercritical gas at 10 MPa and ca. 130 °C [131]. Benzene was used as solvent and ethylene as extractant.

The solubility of oleic, stearic, and behenic acids in supercritical carbon dioxide has been investigated at 40 and 60 °C and 10 – 25 MPa. A significant enrichment of oleic acid compared to stearic acid is observed only above 20 MPa [132]. Enrichment depends on the rate of material transfer and on the relative rates of movement of the phases, so that a separation can be expected after brief extraction [133].

High-purity oleic, linoleic, and linolenic acids have been prepared by means of liquid – liquid extraction, with solvent pairs such as furfural – hexane and ethanol – petrol ether [134].

Separation in the Presence of Acid Soaps. In the system soap – fatty acid – water, micelles known as “acid soaps ”form at certain concentrations [135]. Acid soaps of saturated acids crystallize from aqueous solution, whereas those of unsaturated acids remain in solution. Thus two fractions are obtained with differing degrees of saturation [136].

3.4. Modification of Fatty Acids

3.4.1. *Hydrogenation*

Catalytic hydrogenation of unsaturated fatty acids can be carried out in such a way that the carboxyl group is retained and saturated fatty acids are formed [137] by addition of hydrogen. Because of the increase in the degree of saturation, the melting point of the fatty acids increases. This process is generally known as hardening. Hardening of fatty acids usually means complete saturation of the carbon – carbon double bonds down to an iodine value less than 1. In this way, light-colored fatty acids are obtained which are thermally more stable and resistant to oxidation. Starting materials are, for example, split fatty acids from tallow, the stearin fraction from the olein – stearin separation process, fatty acid fractions from rapeseed oil (erucic acid), and lauric acid, and acid oils from the refining of edible oils. A short overview on fatty acid hydrogenation is given in [138].

Chemistry and Reaction Conditions. The hardening reaction, i.e., the addition of hydrogen to the double bonds of unsaturated fatty acids, is exothermic. Like other types of heterogeneous catalysis, the reaction proceeds in stages [49]:

$$\text{Linolenic acid}(C_{18:3}) \xrightarrow[k_3]{H_2} \text{Linoleic acid}(C_{18:2}) \xrightarrow[k_2]{H_2} \text{Oleic acid}(C_{18:1}) \xrightarrow[k_1]{H_2} \text{Stearic acid}(C_{18})$$

Highly unsaturated fatty acids are hydrogenated more rapidly than monounsaturated fatty acids ($k_3 > k_2 > k_1$). Hydrogenation is accompanied by isomerization processes in which double bonds migrate (conjugation) and geometrical changes occur (*cis – trans* isomerism) [139]. Because fatty acid hardening is carried out predominantly to achieve complete saturation, the selectivity of the reaction (i.e., the ratio k_3: k_2 (2 – 3) or k_2: k_1 (10 – 50) ⟶ Fats and Fatty Oils) is only of importance in some special cases [140]. It has more relevance in oil hardening, e.g., of soybean or rapeseed oil to achieve higher concentrations of monounsaturated acids by selective hydrogenation of the linolenic and linoleic content.

To some extent, the fatty acid reacts with the nickel catalyst, particularly in the absence of hydrogen and in the presence of water, to form nickel soaps [141], [142]:

$$Ni + 2RCOOH \rightleftharpoons Ni(OOCR)_2 + H_2 \quad \text{and} \quad NiO + 2RCOOH \rightleftharpoons Ni(OOCR)_2 + H_2O$$

Because nickel soaps are catalytically inactive, this reaction blocks the active surface of the catalyst. To reduce soap formation, the reaction with hydrogen is carried out at higher pressure [143], generally 2.0 – 3.0 MPa, and the fatty acids are predried. Despite these precautions, catalyst consumption is appreciably higher in the hardening of fatty acids than in hydrogenation of the corresponding triglycerides. The rate of hydrogenation increases initially with increasing temperature, then passes through a maximum in the range of 180 – 210 °C depending on the fatty acid used, and finally decreases [144]. Starting temperature of the reaction is in practice about 150 °C. Hydrogen transport through the liquid to the surface of the catalyst is dependent on the presence of large interfaces between the phases. Hardening is therefore carried out with intensive mixing by means of stirrers or circulation pumps. Newer developments show that sound waves also are suitable to accelerate the reaction [145]. The influence of various reaction parameters on the reaction rate of fatty acid hardening [146] is illustrated in Figure 32.

Figure 32. Effect of operating variables on the reaction rate of fatty acid hydrogenation

The average practical reaction rate corresponds to a reduction of the iodine value by 1 – 2 units per minute. A reduction of 1 in the iodine value corresponds to the consumption of ca. 1 m^3 (STP) of hydrogen per cubic meter of fatty acid and results in a temperature increase of ca. 1.5 °C.

It was further found that formation of nickel soap in the absence of hydrogen depends on temperature and is relatively fast, especially at temperatures normally used for hydrogenation [147]. This has an impact on the remaining nickel content of the hydrogenated fatty acid and subsequently of the distillation residue.

Catalysts. The hardening of fatty acids on a commercial scale is mostly carried out with nickel-based heterogeneous catalysts in slurry form. Dry reduced carrier catalysts (nickel on silica) with high activity and a good resistance to poisoning are used. The active surface of this type of catalyst has been increased to over 100 m^2/g. The pore diameter of the carrier must be large enough (ca. 3 nm) to allow transport of fatty acid molecules to the nickel crystallites. The nickel carrier catalyst is pyrophoric in its activated form. For safer transport and handling, the catalyst is passivated temporarily by a coating of hydrogenated fat and normally sold as pellets in drums. A typical catalyst has the following composition: 20 – 25 % nickel, 10 – 15 % silica, and 60 – 65 % fat. Catalyst consumption depends on the properties of the feedstock and the intended reduction in iodine number, as well as on the hardening conditions. Therefore prior laboratory trials are useful. A gross catalyst consumption of 0.2 – 0.4 % relative to the feedstock is the normal range. Detailed selectivity data of nickel catalysts are given in [148].

Higher selectivity is obtained when heterogeneous copper or palladium catalysts are applied [149]. Homogeneous catalysis by a liquid – liquid two-phase technique with a solvent-stabilized palladium colloid is described in [150].

A number of other catalysts have been described [151]. Acid- and poison-resistant catalysts in pellet form have been investigated for continuous hydrogenation of fatty acids in a fixed-bed process. Catalysts in pellet form based on noble metals are acid resistant, but they are deactivated rather quickly, especially when crude fatty acids are used as feedstock [152].

Manufacturing Procedure. In principle, the same plants can be used for the hydrogenation of fatty acids and for the hardening of oils. Plants in which fatty acids are processed, however, require stainless steel as construction material. The reactor is designed for pressures up to ca. 3.5 MPa. An increasing number of hardening plants operate continuously. The economics of batch operation have been improved significantly by heat recovery systems [153]. Despite good acid resistance of the catalyst, after filtration the hardened fatty acids still contain nickel soap. To minimize this content, the reactor should be discharged by the hydrogen pressure and the hardened fatty acid should be cooled (heat recovery) to about 80 – 120 °C before filtration under ambient conditions. The hardening step is usually followed by distillation to remove the nickel soap and to free the hardened fatty acids from the odor that arises during hardening.

Figure 33 shows a typical batch hardening plant. Hardening is carried out in batches of 5 – 30 t. Thorough mixing by effective agitators keeps the catalyst suspended and the hydrogen well dispersed.

Figure 33. Batch hydrogenation plant

a) Dryer; b) Autoclave; c) Cooler; d) Filter

Particularly thorough mixing is achieved with the reaction loop designed by Lurgi or by Davy Process Technology (formerly Buss); see ⟶ Fats and Fatty Oils). This process can be carried out batchwise in a single reactor or nearly continuously by using several reactor loops in series [154], [155].The plant can also be equipped with a heat recovery system.

In the continuous slurry hardening process developed by Lurgi, a mixture of dried fatty acid, nickel catalyst slurry, and hydrogen is fed into the bottom of the reactor which consists of several chambers. The fatty acid passes through the reactor only once, while the excess of hydrogen is recycled (⟶ Fats and Fatty Oils).

Alternatively, continuous hardening can also be carried out in fixed-bed reactors in the presence of a noble metal (e.g., palladium) pellet catalyst [156]. The feedstock, together with the hydrogen, directly enters the trickle bed at the top of the mixed-phase reactor. The process is free of any slurry handling and eliminates metal soap formation and therefore nickel contamination and nickel residues. A process designed by Lurgi [157] is shown in Figure 34. Also fixed-bed reactors in form of tube-bundle reactors can be used. Such equipment was also developed for the hydrogenation of fatty methyl esters to fatty alcohols [158]. The major advantage is that the tubes filled with the catalyst pellets can be cooled very effectively to remove the exothermic heat and to avoid hot spots. A simulation program for the scale-up of trickle bed hydrogenation reactors are described by [159].

Figure 34. Continuous hydrogenation with fixed bed reactor (Lurgi AG)

3.4.2. *Double-Bond Isomerization*

Isomerization can be split in two main fields of commercial interest: isomerization of monoenes (*cis/trans*) and isomerization of dienes (conjugation).

Monoene Isomerization. Natural fatty acids occur mostly in the higher energy *cis* configuration. The conversion of oleic acid (*cis* configuration) into elaidic acid (*trans* configuration) is carried out industrially by treating oleic acid with sulfur dioxide, oxides of nitrogen, selenium, or acid-activated earths at 100 – 200 °C. The rearrangement reaches an equilibrium at 75 – 80 % elaidic acid [160-162].

Partial hydrogenation of polyunsaturated fatty acids always increases the proportion of *trans* isomers. Therefore, this process can be used specifically for the preparation of technical elaidic acid. Selective partial hardening of oils for the food industry is carried out to increase the melting point of the oil. In this case low *cis-trans* isomerization is of interest. Today *trans* fatty acids are avoided in food applications because of negative health effects on blood cholesterol levels [163]. It was found that temperature, pressure, and catalyst type are the main parameters for formation of *trans* isomers. Operating at lower temperature and higher pressure with a noble metal catalyst results in a large drop in *trans* formation but also reduced selectivity [164-167].

Reduced formation of *trans* fatty acids was also achieved by using special types of zeolites suitable for triglycerides as well as for fatty acids [168], [169].

Another way to control of the melting point of fats without any problems with *trans* isomers is interesterification of completely saturated triglycerides with unhydrogenated oils (mostly *cis*).

Diene Isomerization. The conjugation of dienoic fatty acids has some commercial importance because of the higher reactivity of conjugated unsaturated fatty acids in technical applications such as alkyd resins and because of effects of single isomers in human nutrition [170]. Conjugated systems for technical applications are formed by alkali-catalyzed isomerization of nonconjugated fatty acids, e.g., fatty acids from sunflower or soybean oil:

$$-CH_2-CH=CH-CH_2-CH=CH-CH_2- \rightarrow -CH_2-CH_2-CH=CH-CH=CH-CH_2-$$

The conjugation of diene fatty acids is carried out by saponification with an aqueous alkali solution and heating with excess alkali to 200 – 300 °C. The soap paste is treated with mineral acid to recover the fatty acid mixture. The degree of conjugation achieved is 95 % [171], [172]. The conjugated diene fatty acids obtained are partially isomerized, so that a mixture of the *cis-cis*, *cis-trans*, *trans-cis*, and *trans-trans* configurations is formed.

For the more selective preparation of conjugated linoleic acid isomers, a catalytic isomerization process starting from the monoester of linoleic acid has been developed [173]. This process leads mainly to the 9-*cis*-11-*trans* and the 10-*trans*-12-*cis* isomers and avoids the formation of other species. Due to growing scientific interest in the biological effects of the single isomers [174], a synthesis of the pure 9-*cis*-11-*trans* isomer starting from ricinoleic acid has also been published [175], [176].

3.4.3. *Dehydration*

Fatty acids with a hydroxyl group in the carbon chain can be dehydrated. Ricinenic acid is obtained by dehydration of ricinoleic acid [177]. Ricinenic acid is a mixture of ca. 30 % conjugated 9,11-linoleic acid and ca. 50 % unconjugated 9,12-linoleic acid. The double bonds are partly in the *trans* configuration. By subsequent conjugation, a ricinene fatty acid with an increased content of conjugated double bonds can be prepared. A similar process is known for the dehydration of castor oil (⟶ Drying Oils and Related Products).

3.4.4. *Dimerization*

Unsaturated fatty acids can undergo self-condensation reactions to form high molecular weight dibasic and polybasic acids. Thermal condensation of unsaturated fatty acids was reported in the early 1900s [178], [179] and patents for commercial processes were issued to Emery Industries in 1949 [180] and 1953 [181]. This thermal condensation is believed to be a Diels – Alder type reaction, and the reaction rates are reported to be proportional to the degree of unsaturation [182], [183]. The products are known as dimer acids (Dicarboxylic Acids, Aliphatic – Dimer Acids). The feedstocks used are generally highly unsaturated C_{18} fatty acids derived from vegetable sources such as tall oil.

By the 1950s patents had been issued for catalytic condensation processes [184], [185]. The catalytic condensation reaction is believed to proceed via a carbonium ion intermediate [186] and is much less dependent on degree of unsaturation, which allows even mono-unsaturated fatty acids (e.g., oleic acid) to condense. The principal process flow sheet is given in Figure 35.

Figure 35. Principle process scheme for dimer production

Dimer acids are known to be a mixture of many chemical isomers with branching in their structure; therefore, they are liquid at room temperature. It was shown that they contain acyclic, cyclic, and aromatic structures, all of which show many isomers [187], [188].

The carbonium ion intermediate in this reaction can also undergo rearrangement to form a branched-chain monomeric acid, which is the source of commercial grades of isostearic acid [182]. The isostearic acid is obtained by hydrogenating the monomer acid and then separating into liquid and solid components. The liquid fraction is termed isostearic acid.

A special type of dimerization is the formation of so-called estolides, which are formed from two or more fatty acids when the carboxyl group of one fatty acid reacts with the double bond or hydroxyl group of another. Estolides are found naturally in some oils (e.g. Euphorbiaceae), but mostly are sythetically produced from ricinoleic acid (12-hydroxy-9-octadecenoic acid) or oleic acid [189], [190], as shown in Figure 36. Also the use of meadowfoam oil fatty acid (64 % C_{20}:1, *cis*-9-eicosenoic acid) has been reported [191]. In principal estolides can be characterized as fatty acid polymers with ester bonds and monocarboxylic acid functionality.

Figure 36. Formation of estolides (A: ricinoleic acid, B: oleic acid)

3.4.5. *Ozonolysis*

Oxidative cleavage of the double bond of oleic acid has been known for many years. This process leads to a C_9 dicarboxylic acid (azelaic acid, ⟶ Dicarboxylic Acids, Aliphatic – Degradative Methods) as main product and to C_9 monocarboxylic acid (nonanoic or pelargonic acid). A first commercial process was introduced in the late 1940s using chromium acid as oxidative agent [192]. Later the oxidative cleavage of oleic acid was carried out with ozone and an oxidative treatment [193], [194]. In the first stage, ozone is added to the double bond of oleic acid. The reaction is carried out preferably at 25 – 45 °C with oxygen containing 1 – 5 % ozone. In a second reaction stage, the ozonide is then split by oxidation with ozone-free oxygen to form crude azelaic and pelargonic acids. This step is carried out at 75 – 120 °C. Afterwards further steps for purification of the crude azelaic acid are necessary [195]. Azelaic acid is used for the production of specialty nylons, ester and polyester for elastomers, polyamide fibers, resins, lubricants, and also in cosmetic applications for skin care and an active ingredient for the treatment of acne vulgaris [196].

3.4.6. *Thermal Decomposition*

Heptanoic acid is produced by Atochem in France by thermal decomposition of esters made from castor oil. At 500 – 600 °C, ricinoleic acid methyl ester decomposes in the presence of water vapor to form oenanthal (heptanal) and undecenoic acid methyl ester. The oenanthal is then oxidized with oxygen to heptanoic acid [197]. The main product, undecenoic acid, is used as starting material in the manufacture of nylon 11 (Rilsan).

The alkaline cleavage of ricinoleic acid or castor oil at higher temperature leads to sebacic acid and 2-octanol as a byproduct [198] (⟶ Dicarboxylic Acids, Aliphatic – Degradative Methods).

3.4.7. *Biooxidation*

In the biooxidation process a terminal methyl group of the fatty acid is transformed into a carboxyl group without shortening the carbon chain. This fermentation method is useful for the production of long-chain dicarboxylic (dibasic) acids (carbon number > C_{12}). The microorganism used in the process is a genetically engineered yeast, *Candida tropicalis* [199]. The process has been developed since 1985, starting with modification of the *Canidida tropicalis* strain [200], [201]. The complex fermentation procedure is followed by extensive downstream processing to produce purified dicarboxylic acids (see Fig. 37) [202-204]. An overview on existing routes for the different carbon chain lengths together with the new possibilities via biooxidation is given in Figure 38. The long-chain dicarboxylic acids are mainly used in polymer and hot-melt adhesive applications.

Figure 37. Process scheme for production of long chain dicarboxylic acids

Figure 38. Existing routes and new route via biooxidation for production of dicarboxylic Acids [205]

DDDA: Dodecanediacid

3.4.8. *Enzymatic Esterification*

Lipases not only catalyze the hydrolysis of glycerides, they can also catalyze the esterification of fatty acids with alcohols to give different esters.

Most nonpolar organic liquids generally deactivate biocatalysts, though many remain active in polar solvents like acetone or water. Modification of the biocatalyst may stabilize it against deactivation. Immobilized lipases have been found to remain active in anhydrous organic solvents [206-211]. This property enables lipases to be widely used as biocatalysts in organic syntheses of various useful esters.

Esterification is the reaction between a fatty acid and an alcohol.

$$\mathrm{RCOOH + R'OH \overset{Lipase}{\rightleftharpoons} RCOOR' + H_2O}$$

Water as a product of the reaction has dramatic effects on shifting the reaction equilibrium. It must be continuously removed from the system to enhance the yield. On the other hand, a certain dynamic water environment should be maintained in order to have high enzyme activity. The removal rate of water from the reaction system should be carefully controlled in order not to dry out the lipase. The most common methods to remove water from the reaction system are vacuum and membrane evaporation, azeotropic solvent distillation, drying agents, and bubbling of dry nitrogen [212].

The development of enzyme immobilization enables the enzyme esterification process to be performed at low water contents. The immobilized enzyme is surrounded with water on the carrier (microaqueous reaction system) while the overall water content of the system is low (see Fig. 39).

Figure 39. Scheme for immobilized enzyme and water content in the reaction system

The immobilization technique enables enzymatic esterification to compete with chemical esterification processes both with respect to operational and capital costs. Production rates of several thousands of kilograms of product per kilogram of immobilized catalyst and operational lifetimes of up to several months in packed-bed reactors or slurry systems encourage use of enzymatic catalysis [213].

At the same time the enzyme process produces pure products with respect to functionality, quality, and health aspects. Due to their high catalytic activity at ambient temperature and under mild reaction conditions it is possible to use their stereoselectivity toward a broad range of substrates and to synthesize enantiomerically pure intermediates [214], [215].

Owing to the solvent capability of most of the alcohols, esterification can be performed in solvent-free, homogeneous systems to increase the economic profitability of the process [216].

Meanwhile a large range of alcohols has been used for the synthesis of a variety of ester compounds. Table 17 lists some examples [212].

Table 17. Products from enzymatic esterification of C_6–C_{26} fatty acids

OH source	Products/applications
Straight-chain alcohols (C_1–C_{18})	biofuel, emollients, cosmetics
Straight chain alcohols (C_{19}–C_{28})	wax esters
Branched chain alcohols (C_3–2_8)	wax esters, lubricants
Glycerol and glycerides	triglycerides, 1,3- or 1,2-diglycerides, 1- or 2-monoglycerides, functional foods, emulsifiers
Glucose, fructose, etc	sugar and fructose esters, active cosmetics, emulsifiers
Sterols	sterol esters, functional foods
Ascorbic acid	ascorbyl esters, food preservative
Glycols	glycol esters, cosmetics

[Top of Page]

4. Production of Synthetic Fatty Acids

Mixtures of saturated fatty acids have been manufactured in the past by oxidation of alkanes, but have no economic relevance today. This process led to fatty acids with odd-numbered and branched carbon chains that were inferior in quality and were therefore mainly used in technical applications [217-220], [221].

Specific fatty acids for technical applications are produced from olefins by hydroformylation and hydrocarboxylation.

At present, no economical synthesis for unsaturated, even-numbered, long-chain fatty acids (e.g., *cis*-9-octadecenoic acid) exists.

4.1. Hydroformylation

In the oxo reaction discovered by ROELEN, carbon monoxide and hydrogen are added to the double bond of olefins to form aldehydes (⟶ Oxo Synthesis). This highly exothermic reaction takes place only in the presence of catalysts at temperatures above 180 °C and pressures of 8 – 30 MPa. Oxidation of the intermediate aldehyde yields the desired fatty acid. By starting with terminal linear olefins, both straight-chain and α-branched-chain fatty acids can be obtained [222]. The ratio of straight-chain to branched-chain fatty acids can be varied by changing the catalyst in the hydroformylation reaction. Suitable catalysts are cobalt compounds or rhodium phosphine complexes. The latter result in a higher percentage of straight-chain compounds. Celanese employs this process [223], [224]. Fatty acids with varying degrees of branching are produced in the range of heptanoic to nonanoic acid.

4.2. Hydrocarboxylation

In a similar reaction, the Koch – Haaf method, carbon monoxide is added to the double bond of olefins in the presence of strong acids. In a second step, the intermediate product reacts with water to form branched-chain fatty acids [225]. Concentrated sulfuric acid, phosphoric acid, hydrogen fluoride, or boron trifluoride can be used as catalyst. The reaction mechanism involves a carbonium ion, which reacts with carbon monoxide to form an acylium ion. This then reacts with water to form carboxylic acid. Fatty acids with highly branched chains result from rearrangement of the carbonium ion. The process operates under mild conditions up to 80 °C and 10 MPa. Shell manufactures Versatic acids by this method (for Koch process see ⟶ Carboxylic Acids, Aliphatic – Carboxylation of Olefins, Koch Process and for Versatic acids see ⟶ Carboxylic Acids, Aliphatic – Versatic Acids and Neo Acids).

4.3. Other Commercial and Noncommercial Fatty Acid Syntheses

A method used for manufacturing special fatty acids is the caustic fusion of alcohols. Hoechst (now Clariant) converts tridecyl alcohol to isotridecanoic acid, and the oleochemical part of Henkel (now Cognis) produces isopalmitic acid from the C_{16} Guerbet alcohol (⟶ Fatty Alcohols – Guerbet Alcohols) made from caprylic alcohol [226], [227].

Furtheron Akzo was investigating the addition of acetic anhydride to linear terminal olefins (telomerization). After hydrolysis of the intermediate product, branched-chain fatty acids with high molecular masses and low melting points are obtained, which are especially useful in the manufacture of synthetic lubricants and enamels [228], [229].

Many other processes for making synthetic fatty acids have been developed to the stage of technical feasibility. However, no synthesis can compete economically with the less expensive natural fatty acids. For example, hydrocarboxylation of olefins or acetylene with carbon monoxide and water in the presence of metal carbonyl catalysts (Reppe reaction, ⟶ Carbonylation – Introduction, ⟶ Carbonylation – Carbonylation of Alkynes, ⟶ Carbonylation – Carbonylation of Alkenes) has not yet been used for the commercial production of fatty acids, although this reaction has been the subject of intensive work by several firms [31], [57], [230], [231].

Likewise, oxidation of olefins with air, ozone, chromium trioxide, potassium permanganate, or other compounds has not resulted in an economical manufacturing process. Oxidation of fatty alcohols with air or oxygen has also not been commercially successful. Reaction of trialkylaluminum (obtained as an intermediate in the Ziegler alcohol synthesis, ⟶ Fatty Alcohols) with carbon dioxide under pressure has not led to a usable process.

[Top of Page]

5. Analysis

A number of wet chemical and physical methods are used for quality control of commercial products and identification of individual fatty acids. The composition of fatty acid mixtures and natural fats is best determined by gas chromatography, which allows the identification of individual fatty acids with great accuracy. Whereas fatty acid mixtures up to a chain length of 20 carbon atoms can be analyzed directly, fatty acids having a longer carbon chain must first be converted to their methyl esters to increase accuracy. Natural oils and fats must first be saponified and then derivatized or analyzed directly depending on the nature of the oil. Gas chromatography also allows determination of *cis/trans* contents or composition of conjugated isomers. Nuclear magnetic resonance (NMR) and infrared (IR) spectroscopy have been successfully applied to the determination of the molecular structure of fatty acids.

Many chemical data determined by wet analysis are used to characterize commercial fatty acids and to check their purity [49]. Important parameters are the acid value, saponification value, iodine value, and content of unsaponifiable matter (⟶ Fats and Fatty Oils – Chemical Methods). From the *acid and saponification values*, the average molecular mass and thus the average chain length of the fatty acids can be calculated. If a distilled fatty acid contains no esters or anhydrides components the saponification value is identical to the acid value. The difference between the saponification and acid values is the so-called *ester value*.

The *iodine value* is a measure of the total unsaturation of a fatty acid but does not permit conclusions to be made about the content of saturated fatty acids. Thus, oleic acid has the same iodine value (90) as a fatty acid consisting of a 1 : 1 mixture of stearic and linoleic acids.

Practically all technical-grade fatty acids contain small quantities of foreign substances which do not have carboxyl groups and are therefore not saponifiable. These constituents of natural fatty acids arise from foreign material in the fats, natural byproducts of the organisms that also generated the oil or fat, or from decomposition products. The *content of nonsaponifiable material* in technical-grade fatty acids is regarded as a quality criterion and is usually in the range of 0.5 – 2 %.

Based on the composition of the fatty acids determined by gas chromatography, analytical data, normally obtained by traditional wet chemical analysis as acid or saponification value or iodine value, can also be calculated. The calculation is the more exact the lower the content of unsaponifiables is.

Important physical data for characterizing fatty acids are the solidification point, sometimes called titer, the cloud point, and the color. The *solidification point* is the temperature at which a fatty acid begins to solidify and is defined as the temperature maximum resulting from the release of the heat of crystallization.

Low-melting technical fatty acids without sharp solidification temperatures (< ca. 15 °C) are characterized by the *cloud point*, i.e., the temperature at which a clearly perceptible turbidity occurs.

The measurement of *color* is also used to specify the quality of fatty acids. Color determination can be carried out by comparison with either standard solutions (APHA, Hazen) or colored glass standards (Lovibond, Gardner, F.A.C.). APHA/Hazen define their standards as aqueous solutions made of inorganic salts in given concentrations. Today for all methods the determination itself is mostly no longer carried out by subjective visual comparison but by means of automatic spectrometers. Instead of the Lovibond yellow and red colors it is also common to use the percentage transmission at defined wavelengths, e.g., at 440 and 550 nm.

Analytical methods are standardized and well documented in compendia issued by different associations. Important ones are ISO, AOCS, and DGF [232-234] (see Table 18).

Table 18. Common analytical methods for fatty acids

Method	ISO	AOCS	DGF
Acid value	660	Te 4a-70	C-V 2
Saponification value	3657	Tl 1a-64	C-V 3
Iodine value	3961	Tg 1a-64	C-V 11d
Unsaponifiables	3596-1	Tk 1a-64	C-III 1a
Titer	935	Tr 1a-64	C-IV 3c
Cloud point		Cd 15-78	D-III 3

Gas chromatography	5508	Ce 1e-91	C-VI 10

[Top of Page]

6. Storage and Transportation

Storage. Fatty acids are unstable in the presence of atmospheric oxygen. As with fats, autoxidation of fatty acids leads to the formation of hydroperoxides, which decompose to oxygen-containing products such as aldehydes, ketones, and hydroxy compounds. Other secondary products, such as polymers and splitting products, can also be found [31], [235-238].

The effect of atmospheric oxygen on fatty acids depends primarily on the temperature, the number of double bonds, and the molecular structure. Saturated fatty acids show little tendency to undergo autoxidation, whereas unsaturated fatty acids, and especially polyunsaturated acids, are very susceptible in this respect. Higher temperatures favor the reaction. Small quantities of other substances present either naturally or adventitiously in the fatty acids can act as pro- or antioxidants. All vegetable oils and fats contain, for example, tocopherols as natural antioxidants. In general, vegetable oils have a higher tocopherol content than animal fats and therefore are usually more stable than animal fats with an equivalent degree of unsaturation. On the other hand, metals such as copper and iron (in the form of soaps) act as prooxidants [49].

Autoxidation products affect the color stability of fatty acids, produce a pungent, rancid odor, and alter characteristic analytical values. The content of nonsaponifiable matter and the ester value increase; the acid value and the iodine value decrease. The peroxide value is a measure of the degree of oxidation [239]. The stability of commercial fatty acids cannot be predicted reliably from the analytical data because the relationship of the raw material, manufacturing process, and storage conditions to the autoxidation behavior is very complex.

Synthetic antioxidants are not normally used in manufacturing, but they may be necessary for special applications of technical-grade fatty acids. Thus, up to 0.5 % 2-naphthol is added to oleic acid used as a lubricant in the textile industry. This reduces the tendency to self-heating as a result of autoxidation (Mackey test). Other widely used synthetic antioxidants for fatty acids are butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and *tert*-butyl hydroquinone (TBHQ), which are used for stabilization of oils and fats as well as for fatty acids. They are approved in many countries for food, drugs, and cosmetics [49], [238]. Concentrations in the order of 0.01 % have proved sufficient. With regard to health and safety, fatty acids can alternatively be stabilized by natural antioxidants such as tocopherols and their esters in concentrations on the order of 0.1 % [240-242].

Fatty acids are stored in liquid or solid form. In most cases, liquid fatty acids are kept in heated tanks. Stainless steel and aluminum are the construction materials normally used for tanks and pipelines. Storage temperature should be slightly above the solidification point.

Under these conditions, saturated fatty acids can be stored for several weeks without detrimental effects on quality; however, with some unsaturated fatty acids, the color deteriorates after a few days. Stability can be improved by storage under a nitrogen blanket.

Transportation. Railway tank cars, tank trucks, containers, ships, and aircraft are used for transporting liquid fatty acids. Materials and temperature correspond to those used for storage. Dispatch in steel drums lined with a protective, fatty acid-resistant coating or in plastic drums is less important.

Because of their corrosiveness, short-chain $C_6 – C_9$ fatty acids are subject to international regulations for the transportation of dangerous goods. This no longer applies to C_{10} or mixtures of C_{10} and C_{12} fatty acids, which must be labeled as irritant. Mixtures with main component C_8 such as $C_8 – C_{10}$ must be labeled as corrosive. Mixtures with main component C_{12} such as $C_8 – C_{14}$ or $C_{12} – C_{18}$ fatty acid fractions from palm kernel must be labeled as irritant. Special labeling and handling are not required for C_{14} and longer chain fatty acids. An overview on the classification for road (ADR), railroad (RID), inland water (ADNR), marine (IMDG), and air transport (IATA) is given in Table 19.

Table 19. Transport and safety classifications of fatty acids

Related to	Hazard symbol[a] ADR, RID, ADNR, IMDG, IATA	Tranport class no. ADR, RID, ADNR, IMDG, IATA	Transport UN no. ADR, RID, ADNR, IMDG, IATA	Hazard ident. no. ADR, RID	Packaging group IMDG, IATA	WGK[b]	Storage class VCI[c]
C_6	C	8	2829	80	III	1	8A
C_8	C	8	3265	80	III	1	8A
C_8–C_{10} (main C_8)	C	8	3265	80	III	1	8A
C_{10}	Xi					1	10
C_{12}	Xi					1	11
C_8–C_{14} (mainly C_{12})	Xi					1	10
C_{12}–C_{18} (mainly C_{12})	Xi					1	11
$\geq C_{14}$							11

[a]C = corrosive, Xi = irritant. WGK = Wassergefährdungsklasse (water-endangering class) according to German VwVwS of May 17, 1999, Appendix 1/2 (1 = slightly water-endangering product). VCI = Verband der chemischen Industrie (Association of the German Chemical Industry).

In compliance with EEC directives [243], members of the European Association of Fatty Acid Producing Countries (Association Européenne des Producteurs d'Acides Gras, APAG) have worked out a uniform method of labeling for Europe [244]. All available data on the transported product (including toxicity data), protective measures for storage and handling, and measures to be taken in case of accidents and fires are specified in the respective safety data sheets.

[Top of Page]

7. Environmental Protection, Toxicology, and Occupational Health

Organic substances such as fats and their components (fatty acids and glycerol) are major constituents of wastewater streams from industrial plants engaged in oleochemistry and in processing natural fats and oils or their fatty acids. In domestic wastewater streams, these substances are also ubiquitous components and originate from soaps, kitchen waste and foodstuffs.

Whereas saturated fatty acids of a chain length of 14 or higher are not classified as being a danger to water (German water-endangering class WGK 0: generally not water-endangering) because they have low toxicity and are easily biodegradable, saturated acids up to C_{12} and unsaturated fatty acids are classified as slightly water endangering (WGK 1). However none of the fatty acids is classified as environmentally dangerous with respect to the EEC directive [243]. When industrial plants discharge their wastewater into municipal sewage systems for joint treatment with domestic wastewater, a certain pretreatment may be required. Simple gravitational separation is often sufficient due to the low solubility of fatty acids in water. If necessary addition of traces of sulfuric acid and/or a surfactant greatly enhances the degree of separation. Emulsified fatty acids are separated and skimmed, whereas dissolved fatty acids remain in the wastewater. The latter fatty acids are mostly short-chain types originating from the vacuum systems of the distillation units.

The operation of sewage treatment plants can be badly disturbed by bulking sludge and scum caused by microorganisms (Type 021N, *Nocardioform actinomycetes*). It was found that native fats are primarily responsible for promoting the growth of the organisms. Therefore, the problems can be eliminated by reducing the load of native fats [245].

The entire organic load of the wastewater is established on the basis of the chemical oxygen demand (COD). The biological oxygen demand (BOD_n) within a certain number of *n* days at 20 °C is a measure of biodegradability achieved by the action of microorganisms [246]. The BOD_5 values of some fatty acids and related compounds are given in Table 20. Under both aerobic and anaerobic conditions, unsaturated fatty acids are degraded more rapidly than saturated acids. The rate of degradation of saturated fatty acids increases with decreasing chain length [31]. Fatty acids fulfil the ultimate (ready) biodegradability pass criterion of 60 % BOD/COD according to EEC directive [247] (method: OECD 301).

Table 20. Values of BOD_5 for fatty acids and related compounds [31]

Component	BOD_5, mg/g
Palmitic acid	1070
Stearic acid	786
Sodium palmitate	1020
Sodium stearate	1200
Sodium oleate	1430
Glycerol	780

In addition to the organic load, often also the heavy-metal load and concentration is limited for wastewater. In the case of fatty acid production Ni plays the main role. Nickel in wastewater results from cleaning processes in the hydrogenation plant or from treatment of distillation residues of hydrogenated acids with mineral acid and water. Nickel content can be reduced sufficiently by carefully handling of the spent catalyst and by final treatment of the contaminated wastewater streams. Precipitation with alkaline agents such as calcium hydroxide can achieve Ni contents of 1 ppm and lower.

Air pollution in the fatty acid industries, which results from the venting of storage tanks, reactors, or other process units, is objectionable due to the resulting odors mainly caused by unsaponifiables and short-chain fatty acids up to capric acid rather than toxic properties. The best way of dealing with odors is combustion. This is performed most economically by leading the exhaust air to the boiler house to replace part of the air normally used for combustion. Solid and liquid residues are processed to form a suspension which is then burned in the boiler house or utilized in special combustion plants for the production of low-pressure steam [248].

The toxicological properties of C_6 – C_{12} fatty acids can be summarized. Their acute oral toxicity LD_{50} in rats is > 2000 mg/kg (method: OECD 401). Therefore, they can be classified as nontoxic [243], [249-253]. Neither MAK nor TLV values have been established. However, fatty acids up to lauric acid are corrosive or irritant, and skin or eye contact should be prevented. The acute fish toxicity (LC_{50}) is about 100 mg/L or more (method: ISO 7346/2).

8. Uses

Fatty acids are used in various branches of industry as the acids themselves or in the form of derivatives such as soaps, esters, alcohols, or amides [49], [31], [254], [255], [256]. The shares of the main end-use sectors consuming fatty acids are given in Table 21 for Europe and worldwide consumption [255], [257-259].

Table 21. Main applications of fatty acids in 2003

	Europe %	World, %
Detergents, personal care, soaps, cosmetics	40	49
Plastics	14	10
Rubber and tire industry	7	6
Lubricants and greases	6	3
Paper chemicals	5	3
Protective coatings and resins	5	3
Others (food, feed, candles, textile, leather, adhesives, agrochemicals, construction . . .)	23	26
	100	100

The main end-use sectors as function of applied fatty acid C chain is shown in Table 22 [256].

Table 22. Main applications of fatty acids as function of C-chain

Product	C_8-C_{10}	C_8	C_{10}	C_{12}	C_{14}	C_{16}	$C_{18:1}$	C_{18}	C_{20}-C_{22}	C_{22}
	Coconut- and Palmkernel Oil					Palm oil	Tallow, soybean oil, rapeseed oil		Rapeseed oil (erucic rich)	
Soaps, detergents										
Cosmetics										
Textile										
Coatings and Inks										
Rubber, tyres										
Candles, waxes										
Plastics										
Paper, leather										
Lubricants										
Emulsifiers										
Food										

One of the oldest applications of fatty acids is in the manufacture of candles. Stearin (saturated C_{16} – C_{18} fatty acids) has been used for over 150 years as the basic material for this purpose. However, stearin has been replaced largely by paraffin (⟶ Candles).

Fatty alcohols, fatty amines, and fatty acid esters represent important intermediates in many different fields of application. The syntheses of these derivatives are analogous to those of other monocarboxylic acids, and reactivity decreases with increasing molecular mass.

The fatty acid esters include methyl esters, partial glycerides, wax esters (esters of fatty acids with long-chain fatty alcohols), and ester oils (esters of fatty acids with polyalcohols). Fatty acid methyl esters are intermediates in the manufacture of fatty alcohols and fatty acid alkanolamides. The partial glycerides (mono- and diglycerides) of hardened fatty acids in the palmitic – stearic acid range are used in the food industry as emulsifiers in cakes, pastries, and ice cream. Ester oils are used as lubricants for car engines and compressors, hydraulic fluids, and biogreases [260]. Epoxidized fatty acid esters are used as softeners or plasticizers in plastics such as poly vinyl chloride (PVC). Lead and cadmium stearates are good stabilizers for PVC. as are zinc, calcium, calcium – zinc, and barium – zinc stearates. Cadmium has been replaced because of its toxicity. Wax esters of long-chain fatty acids and fatty alcohols are used as external lubricants in PVC processing [261].

In detergents, soaps, and cosmetics, fatty acids are used primarily in the form of their sodium soaps. The sodium soaps used in the manufacture of soap bars are sometimes made from fatty acids or their methyl esters but are still obtained mainly by saponification of neutral oils many of the newer synthetic detergent (syndet) cleansing bars incorporate teh sodium salt of a fatty acid/isethionate ester. Fatty acid alkanolamides and quaternary fatty alkylammonium salts are used in detergents and cosmetics as foam stabilizer, booster, thickening agent, and consistency factor, and as base for shampoos and body cleansing products. Sulfonated fatty acid methyl esters are of interest as readily biodegradable detergents. Esters such as isopropyl myristate and the triglycerides of short-chain fatty acids are employed as the oil component of cosmetics and pharmaceutical products. Metal soaps, such as aluminum, magnesium, and zinc soaps, serve as thickening agents in cosmetic creams. These metal soaps are also used in powders, because of their lubricating properties. Sodium, lithium, and calcium soaps are employed as additives in mineral-oil lubricants for high-performance engines.

Fatty acid amides serve as slip agents and antiblock agents in plastic formulations [261], stabilizers of emulsions and dyes, builders in synthetic detergents, intermediates in the production of textile water repellent [49], and as components for agricultural chemicals such as pesticides.

Fatty acid amines produced from fatty acids via the nitrile route are used in the rubber industry as mold-release and accelerating agents and for reclamation. They are employed as corrosion inhibitors in the metal industry and for flotation of minerals. After quaternization they are applied for preparing cationic softeners in the textile industry, as antistatic agents, for producing cationic surfactants agents, and oil-well drilling auxiliaries.

Both fatty amides and amines can be transformed into nonionic surfactants by reaction with ethylene oxide, whereas processing with chloroacetates yields amphoteric surfactants with betaine structure [257].

Large quantities of fatty acids are required in the production of alkyd resins for surface coatings (e.g., paints and varnishes) used in all areas of coating applications. The polyunsaturated fatty acids obtained from soybean and sunflower oils are reacted with a polyhydric acid such as phthalic anhydride and polyalcohols to form alkyd resins and are especially important for this purpose [254]. Conjugated fatty acids, saturated fatty acids, and short-chain fatty acids are also used in making paints.

Dimer fatty acids from tall, soybean, or sunflower oil are are mainly employed as polyamides for the coatings and paint industry, as well as for hot-melt adhesives and printing inks. Reactive polyamides of dimer fatty acids are effective hardeners for epoxy resins. Isostearic acid as byproduct of the dimerization process is a monofunctional branched-chain fatty acid. Because of their low solidification points (titers) and high oxidative stability its esters and the conversion product isostearic alcohol are especially used for lubricants, cosmetics, and detergents. Isopalmitic acid has the same application areas. Estolides (also one acid function) and estolide esters have growing importance in cosmetics, coatings, and biogradable lubricants. Another special form of acid dimers that have been used for years in the paper industry for paper sizing (surface treatment) are alkyketene dimers (AKD) based on C_{16} – C_{22} saturated fatty acids, which are prepared by dehydrochlorination of the corresponding fatty acid chlorides (⟶ Ketenes – Production and Uses).

Dibasic fatty acids such as azelaic acid (C_9 from oleic acid, see chap. Ozonolysis), sebacic acid (C_{10} from ricinoleic acid, see chap. Thermal Decomposition) and brassilic acid (C_{13} from erucic acid, see Section Biooxidation) find important outlets in form of esters as plasticizers, modifiers, components for lubricants, and for polymers such as PVC and Nylon.

The C_{22} fatty acids erucic acid (monounsaturated) and behenic acid (saturated) from high-erucic rapeseed oil have applications as surfactants, plastics additives (erucaamide, behenamide), and lubricants [262], [263]. Fatty acid distillates of low-erucic rapeseed oil are used as vegetable-based unsaturated C_{18} source. Partial hydrogenation gives a high oleic acid with improved oxidation stability for production of diverse esters or for unsaturated fatty alcohols [264].

Ricinoleic acid as main natural hydroxy acid can be used for direct esters, estolides, fatty amides, or ethoxylates employed for cosmetics, coatings, and lubricants. Undecylenic acid (C_{11}, pyrolysis of ricinoleic methyl ester) is used as starting material in the manufacture of nylon 11 (Rilsan). The hydrogenation of ricinoleic acid leads to 12-hydroxy stearic acid, which is mainly used in lubricant greases [198]. The synthetic production of dihydroxy or polyhydroxy fatty acids involves as first reaction step the epoxidation (⟶ Epoxides) of the base fatty acid (e.g., oleic acid) or oil (e.g., rapeseed, soybean) followed by a catalytic epoxy ring opening in the presence of water or hydrogen donors. Applications exist in polymer additives (PVC), plastics, surfactants, lubricants, and the textile industry.

In the rubber industry, various types of stearin (mixture of C_{16} and C_{18}) are used as lubricants. In tire manufacture, stearic acid is also used as a separating agent during molding. Zinc and magnesium stearates act as accelerators in the vulcanization process. Soaps of diverse fatty acids are used as emulsifiers in emulsion polymerization for the manufacture of synthetic rubber. Stearin also serves as auxiliary for treatment of recycled paper (e.g., deinking) in the paper industry.

Olein, i.e., technical-grade oleic acid, has been used for many years as a lubricant in the textile industry and for leather auxiliaries. Saponification of oleic acid leads to soft soaps. Oleic acid derivatives are employed as wetting, leveling, and finishing agents in many other operations in textile manufacturing. Thus, *N*-methyloleyltaurine is used in dyeing textiles, and sulfonated monoethanolamides are used in washing printed cloths. Finishing agents contain esters and amides of longer chain fatty acids with polyglycols or polyamines. Melamine resins modified with fatty acids serve as impregnating agents. Oleic acids are used for producing fatty alcohols with high oleic content for the cosmetic, detergent, and plastics industries, where they are employed as solvents, oily components, super-fatting agents, defoamers, plasticizers, and emulsifiers. Esters of oleic acid with fatty alcohols such as oleic acid oleyl ester (C_{18} unsatd/C_{18} unsatd) or oleic acid decylester (18 unsatd/C_{10} satd) serve as oily components for cosmetics. Esters of oleic acid with di- or polybasic alcohols such as trimethylolpropane are used for lubricants.

Distillation and fractionation result in bottom products (residues) of 5 – 10 % in relation to the feed crude fatty acid [265]. Coproducts contain free fatty acids in the range of about 25 – 50%. The use as ingredients in feed compounds is limited according to regional laws with respect to heavy metal content and animal origin. APAG reports a maximum of 200 ppm Ni in the fat component and 5 – 20 ppm in the final feed [266]. Owing to mad cow disease (BSE) tallow-based coproducts are not permitted for feeding in Germany [267]. Therefore, an economical outlet for the coproducts in Europe is today mainly thermal utilization as fuel substitute in boiler houses and incinerators of the concrete and steel industry. The heat of combustion depends on the mix and achieves about 70 – 90 % of the value of light crude oil (42 MJ/kg). The allowed Ni content depends on the equipment and license of the end users.

1. Introduction

Fatty alcohols are aliphatic alcohols with chain lengths between C_6 and C_{22}:

$$CH_3(CH_2)_nCH_2OH(n = 4 - 20)$$

They are predominantly linear and monohydric, and can be saturated or have one or more double bonds. Alcohols with a carbon chain length above C_{22} are referred to as wax alcohols. Diols whose chain length exceeds C_8 are regarded as substituted fatty alcohols. The character of the fatty alcohols (primary or secondary, linear or branched-chain, saturated or unsaturated) is determined by the manufacturing process and the raw materials used. Natural products, such as fats, oils, and waxes, and the Ziegler alcohol process provide linear, primary, and even-numbered alcohols; those obtained from

natural sources may be unsaturated. In contrast, the oxo process yields 20 – 60 % branched fatty alcohols, and also some odd-numbered ones. Guerbet dimerization results in α-branched, primary alcohols, whereas Bashkirov oxidation yields secondary alcohols.

Depending on the raw materials used, fatty alcohols are classified as natural or synthetic. Natural fatty alcohols are based on renewable resources such as fats, oils, and waxes of plant or animal origin, whereas synthetic fatty alcohols are produced from petrochemicals such as olefins and paraffins. Up to 1930, when catalytic high-pressure hydrogenation was developed ADKINS and FOLKER [7], NORMAN [8], SCHRAUTH [9], and SCHMIDT [10], the manufacture of fatty alcohols was based almost exclusively on the splitting of sperm oil. By 1962, the world production capacity from natural raw materials had grown to ca. 200 000 t/a. New processes utilizing petrochemical raw materials, e.g., the Ziegler alcohol process, the SHOP process, the oxo process, and the construction of additional plants for high-pressure hydrogenation of natural raw materials, allowed a further increase. In 2005, the world nameplate production capacity of fatty alcohols was estimated to be 2.5×10^6 t/a, being nearly equally based on natural and petrochemical feedstocks. This ratio will change because 600 000 – 700 000 t/a of additional production capacity based on natural feedstocks will come on stream by 2008. Production and consumption were estimated to amount to only 80 % or less of capacity. Fatty alcohols and their derivatives are used in polymers, surfactants, oil additives, and cosmetics and have many specialty uses.

[Top of Page]

2. Saturated Fatty Alcohols

2.1. Physical Properties

Saturated fatty alcohols up to dodecanol are clear, colorless liquids. The next higher homologues are soft materials; tetradecanol and higher alcohols have a waxy consistency. The saturated alcohols crystallize in a nearly orthorhombic lattice [11] and all have a lower specific density than water. The lower members of the series have characteristic odors; the higher fatty alcohols are odorless, except for traces of impurities such as carbonyl compounds and hydrocarbons, which are usually present.

Physical properties of linear, primary fatty alcohols are summarized in Table 1 (for additional data on pure alcohols and commercially important blends, see [12-15]).

Table 1. Physical and chemical properties of fatty alcohols

IUPAC name	Common name	CAS registry number	Molecular formula	M_r	Hydroxyl number	*mp*, °C	*bp*, °C (*p*, kPa)	Density, g/cm³ (*t*, °C)	Refractive index (*t*, °C)
1-Hexanol	caproic alcohol	[111-27-3]	$C_6H_{14}O$	102.2	548	–52	157	0.819 (20)	1.4181 (20)

1-Dotriacontanol	lacceryl alcohol	[6624-79-9]	$C_{32}H_{66}O$	466.9	120	89		
1-Tritriacontanol		[71353-61-2]	$C_{33}H_{68}O$	480.9	116			
1-Tetratriacontanol	geddyl alcohol	[28484-70-0]	$C_{34}H_{70}O$	494.9	113	92		

Boiling points and melting points increase uniformly with chain length. Both are significantly higher than those of the hydrocarbons with the same number of carbon atoms. The influence of the polarizing hydroxyl function diminishes with increasing chain length. Thus hexanol and even octanol show some water solubility, but decanol and the higher fatty alcohols can be considered as immiscible with water. However, a slight hygroscopicity is observed even with octadecanol and higher fatty alcohols, which can absorb water vapor from air during storage. Common organic solvents such as petroleum ether, lower alcohols, and diethyl ether are suitable solvents for fatty alcohols.

2.2. Chemical Properties

The industrial importance of the fatty alcohols is due to the large number of reactions that the hydroxyl group may undergo. Figure 1 shows some typical examples (see also ⟶ Alcohols, Aliphatic); many of the resulting derivatives are intermediates of commercial importance (see section Uses). Ethoxylation with ethylene oxide yields fatty alcohol polyglycol ethers, which are of major importance for the detergent industry (⟶ Laundry Detergents; ⟶ Surfactants):

$$RCH_2OH + nH_2C\underset{O}{\diagdown\diagup}CH_2 \longrightarrow RCH_2(O-CH_2CH_2)_nOH$$

Figure 1. Typical reactions of fatty alcohols

Under normal conditions, fatty alcohols are resistant to oxidation. However, they can be converted into aldehydes or carboxylic acids using strong oxidants or by catalytic oxidation with air or oxygen [16-20]. This reaction is important for the synthesis of C_6 – C_{10} aldehydes if these are not readily available from natural sources [21] and are therefore produced from synthetic alcohols.

2.3. Production from Natural Sources

Two groups of natural raw materials are used for the production of fatty alcohols: (1) fats and oils of plant or animal origin, which contain fatty acids in the form of triglycerides that can be hydrogenated after suitable pretreatment (⟶ Fats and Fatty Oils – Refining) to yield fatty alcohols; and (2) wax esters from whale oil (sperm oil), from which the fatty alcohols are obtained by simple hydrolysis or reduction with sodium. The commercial exploitation of sperm oil has led to depletion of whale populations and is banned in some countries. Attention has therefore turned to the jojoba plant whose oil also consists of wax esters. Successful attempts to cultivate this desert shrub and develop it as a source of raw material have been made. But this wax is mainly used in cosmetic applications in a small amount.

Most fatty chemicals obtained from natural sources have chain lengths of C_{16} – C_{18}. The limited availability of compounds with 12 – 14 carbon atoms, which are important in surfactants, was one of the driving forces behind the development of

petrochemical processes as well as the intensification of plantation and the breeding of new crops for the production of fatty alcohols (see Section Synthesis from Petrochemical Feedstocks). Higher alcohols, such as C_{20} – C_{22} alcohols, can be produced from rapeseed oils rich in erucic acid and fish oils. Unsaturated fatty alcohols may be manufactured in the presence of selective catalysts. Hydroxyacids for production of diols are available from castor oil. For detailed reviews of large-scale industrial processes for the production of fatty alcohols, see [1], [22], [23].

2.3.1. *Hydrolysis of Wax Esters*

The hydrolysis of wax esters is of minor importance today. It is carried out by heating sperm oil with concentrated sodium hydroxide at ca. 300 °C and distilling the alcohol from the sodium soap.

$$R^1-\overset{\overset{\displaystyle O}{\|}}{C}-OR^2 + NaOH \longrightarrow R^1-\overset{\overset{\displaystyle O}{\|}}{C}-ONa + R^2OH$$

The distillate consists of partially unsaturated C_{16} – C_{20} alcohols, which are hardened by catalytic hydrogenation to prevent autoxidation. Since sperm oil contains only ca. 70 % wax esters, the alcohol yield is about 35 %.

2.3.2. *Reduction of Wax Esters with Sodium*

The reduction of esters with sodium was first described in 1902 by BOUVEAULT and BLANC (for a review, see [24]). Large-scale application of this process was achieved in 1928 (Dehydag).

$$\begin{aligned} &R^1-\overset{\overset{\displaystyle O}{\|}}{C}-OR^2 + 4\,Na + 2\,R^3OH \longrightarrow \\ &R^1CH_2ONa + R^2ONa + 2\,R^3ONa \xrightarrow[-4\,NaOH]{+4\,H_2O} \\ &R^1CH_2OH + R^2OH + 2\,R^3OH \end{aligned}$$

Molten sodium is dispersed in an inert solvent and the carefully dried ester and alcohol are added. When the reaction is complete, the alkoxides are split by stirring in water, and the alcohols are washed and distilled [25].

The added alcohol R^3OH, preferably a secondary alcohol, acts as a hydrogen donor. Because of side reactions, the consumption of sodium can be as much as 20 % above the stoichiometric requirement.

The reduction proceeds selectively without production of hydrocarbons and isomerization or hydrogenation of double bonds. Extensive safety measures are required due to the large quantity of metallic sodium used. The process was used until the 1950s to produce unsaturated fatty alcohols, especially oleyl alcohol from sperm oil. These alcohols can now be produced by selective catalytic hydrogenation processes using cheap raw materials, and the sodium reduction process is of interest only in special cases. A fully continuous plant with a production capacity of 3600 t/a was built in Japan in 1973 for the reduction of sperm oil [26].

2.3.3. *Hydrogenation of Natural Raw Materials*

2.3.3.1. *Raw Materials and Pretreatment*

For the production of C_{12} – C_{14} alcohols, preferably coconut oil and palm kernel oil are used. Rape seed oil, palm oil, soybean oil, and tallow are the main sources for C_{16} – C_{18} alcohols. Rapeseed oil rich in erucic acid yields fatty alcohols with 20 or 22 carbon atoms. Bifunctional fatty alcohols can be obtained from castor oil and other special oils (see Chap. Bifunctional Fatty Alcohols). More than 90 % of the 125 × 106 t/a of vegetable oils are used in food applications.

Before hydrogenation, contaminants such as phosphatides, sterols, or oxidation products and impurities such as seed particles, dirt, and water are removed in a cleaning stage, which includes refining by treatment with phosphoric acid, centrifugation, and adsorption, e.g., on charcoal or bentonite (⟶ Fats and Fatty Oils – Refining).

The refined triglycerides are then hydrolyzed to yield fatty acids (⟶ Fatty Acids) or transesterified with lower alcohols to yield fatty acid esters.

Refined free fatty acids, wax esters, and fatty acid methyl esters are used for hydrogenation. Direct hydrogenation of triglycerides is also possible; however, under the reaction conditions, glycerol is reduced to propylene glycol and propanol and therefore makes no commercial contribution as a byproduct. More hydrogen is needed and catalyst costs increase. Therefore, triglyceride hydrogenation is not used industrially.

Fatty acid esters are produced either by esterification of free fatty acids or by transesterification of triglycerides (see also ⟶ Esters, Organic).

Esterification of Fatty Acids. Esterification is an equilibrium reaction:

$$R^1-CH_2-\overset{\overset{\displaystyle O}{\|}}{C}-OH + R^2OH \rightleftharpoons R^1-CH_2-\overset{\overset{\displaystyle O}{\|}}{C}-OR^2 + H_2O$$

Excess alcohol or removal of water shifts the equilibrium toward ester formation. Industrial esterification is carried out in a column at 200 – 250 °C under slight pressure and with excess methanol. Some processes use a catalyst like an ion

exchanger [27]. Distilled fatty acids, which no longer have the composition of the original natural product, are predominantly used. Methanol reacts with the fatty acid in a countercurrent. The acid number (milligrams of KOH needed to neutralize one gram of substance) is used as a quality characteristic and for process control. Batch and continuous processes give esters of similar quality, but the continuous process uses less methanol and the residence time is reduced. The methyl ester is subsequently distilled for purification. Another uncatalyzed process esterifies the distilled fatty acid with an excess of fatty alcohols to wax esters at about 200 – 250 °C [28].

Transesterification of Triglycerides. This reaction is carried out continuously with alkaline catalysts. Like esterification, transesterification is an equilibrium reaction and is shifted toward the desired ester by excess methanol or removal of glycerol:

$$\begin{array}{l} CH_2OCOR \\ | \\ CHOCOR \\ | \\ CH_2OCOR \end{array} + 3\,CH_3OH \rightleftharpoons \begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array} + 3\,RCOOCH_3$$

If the reaction is carried out under mild conditions (50 – 70 °C, atmospheric pressure, excess methanol), free fatty acids present in the oils must first be removed or pre-esterified, e.g., with glycerol. Under more severe conditions (i.e., at 9 – 10 MPa and 220 – 250 °C), pre-esterification is unnecessary, and less pure, cheaper raw materials can be used. Disadvantages of the latter process are the need for high-pressure equipment, a greater excess of methanol, and the energy-intensive further processing of the aqueous methanol. The methyl esters are purified by distillation.

Figure 2 demonstrates the production tree of physical and chemical processing of fats and oils.

Figure 2. Physical and chemical processing of fats and oils

2.3.3.2. *Hydrogenation Processes*

Three large-scale hydrogenation processes are used commercially:

1. Gas-phase hydrogenation
2. Trickle-bed hydrogenation
3. Suspension hydrogenation

The first two processes use a fixed-bed catalyst. In contrast to gas-phase and trickle-bed hydrogenation the suspension process uses a powdered catalyst with a specific particle size distribution. The selection of a process depends on the integration into existing plants and the choice of raw materials. In all cases, hydrogenation is carried out with copper-containing, mixed-oxide catalysts at 170 – 270 °C and 4 – 30 MPa. By using proprietary fixed bed catalysts methyl esters can be hydrogenated at 170 – 250 °C and 10 – 40 MPa in a trickle bed [31], [30] or in the gas phase (Fig. 12) [27]. The wax ester process operates at 170 – 270 °C and from less than 10 to 30 MPa (Fig. 13) [28].

Figure 12. Production of fatty alcohols by hydrogenation of fatty acid methyl esters

Figure 13. Wax ester route to fatty alcohols

Suspension Hydrogenation. This process is applicable to fatty acid methyl esters as well as to fatty acids.

Hydrogen (ca. 50 mol per mole of ester) and the heated methyl ester are fed separately into the bottom of a narrow reactor. The reaction is carried out at ca. 25 MPa and 250 – 300 °C in the presence of a fine powdery copper catalyst; the LHSV (liquid hourly space velocity) is approximately 1. The excess hydrogen serves to circulate the reaction mixture. The product mixture is separated into a gas phase, which is recycled to the reactor, and a liquid phase, from which the methanol is stripped. The crude product, which still has a saponification number of 6 – 10 (milligrams of KOH required to saponify one gram of substance), is distilled off after removal of the catalyst. If a stainless steel reactor is used, this process can be applied to the direct hydrogenation of fatty acids. In this case, an acid-resistant catalyst is required, and catalyst consumption is increased.

A variant that is particularly suitable for the hydrogenation of fatty acids has been developed by Lurgi (Fig. 3) [31], [32] [34] and is used by several manufacturers. This process employs a large excess of fatty alcohol in the hydrogenation reactor. Hydrogen, fatty alcohol – catalyst slurry, and fatty acids are fed separately into the reactor; the ester forms almost instantaneously [34] and is then hydrogenated in the same reactor in a slower, second reaction step. Hydrogenolysis is carried out at ca. 30 MPa and 260 – 300 °C. Catalyst consumption is 3 – 7 kg/t fatty acid depending on the acid and the concentration of catalyst-poisoning impurities like sulfur, chloride, and phoshorus. The catalyst is separated by centrifugation, and the crude fatty alcohol, which has an acid number of < 0.1 and a saponification number of 2 – 5, is purified by distillation. The selectivity of the process is > 99 %.

Figure 3. Suspension hydrogenation of fatty acids (Lurgi process)

By continuously replacing part of the spent catalyst, the activity of the copper chromite contact can be held constant.

Gas-Phase Hydrogenation. This process requires a vaporized substrate and is therefore particularly suitable for methyl esters, preferably with a chain length of 12 – 18 C-atoms [34]. Characteristics of the process are a large excess of recycle gas (ca. 600 mol of H_2 per mole of ester), high gas velocities and the addition of methanol to aid evaporation [35], [36]. Decomposition of methanol creates significant quantities of carbon monoxide, water, and dimethyl ether. Admixture of an inert gas to the hydrogen is claimed to make the addition of methanol superfluous and to reduce the excess of recycle gas [37]. Catalysts like copper–zinc or copper–chromium mixed oxides are used in a fixed bed. The conditions required are 4 – 10 MPa pressure and 170 – 230 °C, with an LHSV of about 0.3. Alcohol yields of > 99 % are achieved. Catalyst consumption is < 0.8 kg/t feed. The product mixture is separated into a gas and a liquid phase, the hydrogen recycled and the methanol stripped from the fatty alcohol.

Trickle-Bed Hydrogenation. In this process, the products to be reduced are used in their liquid form. The process is therefore also suitable for methyl esters [31] and non-vaporizable substrates such as wax esters and [28]. Corrosive effects of acids can be neutralized by hydrogenation in the presence of amines [38]. If a considerably lower excess of recycle gas (ca. 100 mol of H_2 per mole of ester) is used, a different plant design is necessary. The reaction is carried out at <10 – 30 MPa and about 170 – 230 °C, with an LHSV of 0.5 – 0.8. Normally, catalysts based on copper, chromium- or copper-zinc mixed oxides are employed. More rarely, supported catalysts such as copper chromite on silica are used. Catalyst consumption is < 0.8 kg/t feed. Further treatment of the product is identical to that described for gas-phase hydrogenation.

Comparison of Hydrogenation Processes. In the case of the fixed-bed processes (gas-phase and trickle-bed hydrogenation), the catalyst need not be separated from the crude fatty alcohol. However, a gradual decrease in the hydrogenating activity due to catalyst poisons such as sulfur, phosphorus, or chlorine is observed, whereas continuous replacement of the catalyst in the suspension process ensures constant activity. If methyl esters are employed, separation and further processing of the methanol is necessary.

Catalysts that contain noble metals, especially rhenium, may allow hydrogenation at lower pressures, which would reduce capital and operating costs [39-41].

2.4. Synthesis from Petrochemical Feedstocks

2.4.1. *Ziegler Alcohol Processes*

Two processes for the production of synthetic fatty alcohols are based on the work of ZIEGLER on organic aluminum compounds: the Alfol process, developed by Conoco, and Ethyl Corporation's Epal process [42], [43]. Fatty alcohols synthesized by these processes are structurally similar to natural fatty alcohols and are thus ideal substitutes for natural products.

Conoco started the first Alfol plant in the United States in 1962. This plant is now operated by Sasol Northe America. In 1964 Condea Chemie (now Sasol) installed a similar plant in Brunsbüttel, Federal Republic of Germany. Ethyl Corporation (today BP/Amoco) developed its own process (Epal process) and began operations in 1964. Additional Alfol alcohol plants were built in Ufa/ Russia in 1981 and in Jilin/ China in 1998.

Alfol process. Figure 4 shows a simplified diagram of the Alfol process [44]. A hydrocarbon is used as solvent. The process involves five steps: hydrogenation, ethylation, growth reaction, oxidation, and hydrolysis.

Figure 4. Alfol alcohol process

1. Hydrogenation

$$2\ Al(CH_2CH_3)_3 + Al + 1\tfrac{1}{2}\ H_2 \longrightarrow 3\ HAl(CH_2CH_3)_2$$

2. Ethylation

$$3\ HAl(CH_2CH_3)_2 + 3\ H_2C{=}CH_2 \longrightarrow 3\ Al(CH_2CH_3)_3$$

3. Growth Reaction

$$3\ Al(CH_2CH_3)_3 + (x+y+z)\ H_2C{=}CH_2 \longrightarrow Al\begin{cases}(CH_2CH_2)_{x+1}H\\(CH_2CH_2)_{y+1}H\\(CH_2CH_2)_{z+1}H\end{cases}$$

4. Oxidation

$$Al\begin{cases}R^1\\R^2\\R^3\end{cases} + 1\tfrac{1}{2}\ O_2 \longrightarrow Al\begin{cases}OR^1\\OR^2\\OR^3\end{cases}$$

5. Hydrolysis

$$Al\begin{cases}OR^1\\OR^2\\OR^3\end{cases} + 2\ H_2O \longrightarrow AlO(OH) + R^1OH + R^2OH + R^3OH$$

Two-thirds of the triethylaluminum produced in the ethylation reaction (b) are recycled to the hydrogenation stage (a), and one-third enters the growth reaction (c). Insertion of the ethylene molecule into the aluminum – carbon bonds occurs as a statistical process and leads to a broad distribution (Poisson distribution [45], [46]) of chain lengths, ranging from C_2 to beyond C_{26} [44]. An optimal yield of the C_{12} – C_{14} alcohols, which are important in the surfactant sector, requires addition of about four molecules of ethylene per aluminum – carbon bond (see also Table 2). A small percentage of olefins are formed as byproducts.

Table 2. Typical alcohol distributions in Alfol and Epal processes

	Distribution, %	
Alcohol	**Alfol process**	**Epal process**
Ethanol	0.5	traces
Butanol	3.4	0.1
Hexanol	9.5	1.5
Octanol	16.1	3.5
Decanol	19.5	8.0
Dodecanol	18.4	34.0
Tetradecanol	14.1	26.0
Hexadecanol	9.1	16.0
Octadecanol	5.1	8.8
Eicosanol	2.5	1.9
Docosanol	1.1	0.2

Because of the varying reactivity of partially oxidized trialkylaluminum compounds, oxidation is carried out stepwise by

passing through carefully dried air. Cooling is necessary, especially at the start of the reaction. Alkanes and oxygen-containing compounds are formed as byproducts [42].

Prior to hydrolysis, the solvent is removed by distillation. Hydrolysis with water gives high-purity hydrated alumina as a coproduct, which has many industrial applications, e.g., in catalytic processes (⟶ Aluminum Oxide – Catalytic Applications) and in ceramics. In the 1960s, hydrolysis was carried out with hot sulfuric acid at Conoco's and Ethyl Corporation's plants. Conoco changed to neutral hydrolysis, but the sulfuric acid method was used in the Epal process until its shutdown and leads to high-purity aluminum sulfate as a coproduct. The crude alcohols are finally fractionated into marketable blends and single cuts.

Epal Process (see Fig. 5). Many attempts have been made to achieve a narrower distribution of chain lengths in the growth reaction [43]. The only process that has been used on an industrial scale is the Epal process developed by the Ethyl Corporation (today BP/Amoco). The reaction steps resemble those of the Alfol process, but the growth reaction is not carried as far. The product of the growth reaction is subjected to transalkylation (290 °C, 3.5 MPa) with $C_4 – C_{10}$ olefins. The chain lengths of the resulting trialkylaluminum compounds are predominantly $C_4 – C_{10}$. Excess olefins are removed in a stripping column and then fractionated. The trialkylaluminum compound is subjected to a second growth reaction and then transalkylated (200 °C, 35 kPa) with $C_{12} – C_{18}$ olefins. Again the olefins are separated in a stripper and fractionated. At this stage, the trialkylaluminum compound consists largely of alkyl chains with 12 – 18 carbon atoms.

Figure 5. Flow diagram of the Epal process

The alcohol distributions achieved in the Epal and Alfol processes are shown in Table 2 [47]. The Epal process offers greater flexibility than the Alfol process because both the alcohols and the α-olefins that are formed as intermediates can be marketed [48]. Disadvantages of the Epal process are the higher capital and operating costs, a considerably more complicated process control, and an increased proportion of branched-chain olefins and alcohols.

2.4.2. *Oxo Process*

The oxo process (hydroformylation) consists of the reaction of olefins with an H_2– CO gas mixture in the presence of suitable catalysts. This reaction was discovered in 1938 by O. ROELEN at Ruhrchemie during work on the Fisher – Tropsch synthesis. Although the first production plant was constructed before 1945 [49], the oxo process achieved industrial importance only in the 1950s, with the increasing demand for plasticizers and detergents. The process is based on the following reaction (for details on the reaction mechanism, see [50] and ⟶ Oxo Synthesis):

$$2R-CH=CH_2 + 2CO + 2H_2 \xrightarrow{HCo(CO)_4} R-CH_2CH_2-CHO + R-\overset{\overset{CH_3}{|}}{CH}-CHO$$

α-Olefins yield approximately equal amounts of straight-chain and branched aldehydes (see also Fig. 10). Internal and branched alkenes can also be used in this reaction. Internal olefins give a product containing some primary aldehyde because the catalyst effects double-bond isomerization.

For a long time paraffin-based processes were predominant as a source of olefins, especially for detergents [48], [57]. With the development of the SHOP process (Shell's Higher Olefin Process), ethylene has become the preferred raw material [58]. The principal steps in the SHOP process are ethylene oligomerization, isomerization, and metathesis (⟶ Hydrocarbons). The products are $C_{12} – C_{18}$ α-olefins and $C_{11} – C_{14}$ internal olefins, which are all important in the area of surfactants [59], [60].

Heterogeneous hydrogenation of the oxo aldehydes at 5 – 20 MPa and 150 – 250 °C in the presence of catalysts based on nickel, molybdenum, copper, or cobalt yields the corresponding alcohols. Alternatively, the aldehyde can be subjected to an aldol reaction as in the production of 2-ethylhexanol (⟶ 2-Ethylhexanol – Industrial Production). A flow sheet of the oxo process is depicted in Figure 6. Worldwide there are three variants of the oxo process [52]: (1) the classical process using $HCo(CO)_4$ as catalyst; (2) the Shell process based on a cobalt carbonyl – phosphine complex [51]; and (3) a process using a rhodium catalyst. The key parameters of these processes are compared in Table 3.

Table 3. Typical process parameters of the oxo processes

Parameter	Oxo process		
	Classical	**Shell**	**Union Carbide**
Catalyst	cobalt carbonyl	cobalt carbonyl – phosphine complex complex	rhodium carbonyl – phosphine complex phosphine complex

Catalyst concentration, %	0.1 – 1.0	ca. 0.5	0.01 – 0.1
CO : H_2 ratio	1 : 1 – 1.2	1 : 2 – 2.5	excess hydrogen
Temperature, °C	150 – 180	170 – 210	100 – 120
Pressure, MPa	20 – 30	5 – 10	2 – 4
LHSV*	0.5 – 1.0	0.1 – 0.2	0.1 – 0.25
Primary products	aldehydes	alcohols	aldehydes
Linearity, %	40 – 50	80 – 85	ca. 90 (*n*-butanol)

* Liquid hourly space velocity

The classical, cobalt-catalyzed oxo process involves the following steps: oxo reaction, catalyst separation and regeneration, aldehyde hydrogenation, and alcohol distillation. Variants of this process differ mainly in the catalyst separation and regeneration steps [53], [54].

In the Shell process, alcohols are obtained directly because of the greater hydrogenating activity of the catalyst; the aldehyde hydrogenation step is unnecessary. Linearity is improved and the 2-methyl isomer is the main byproduct. A disadvantage is the loss of olefins due to hydrogenation to alkanes.

Hydroformylation based on a rhodium catalyst has been used by Union Carbide since the 1970s for the production of *n*-butanol and 2-ethylhexanol [55]. The higher activity of the catalyst enables operation at lower temperature and pressure. For butanol, the linearity is over 90 %. The disadvantage is the high price of rhodium.

For a review of the oxo synthesis, see [56].

Figure 6. Flow diagram of the classical oxo process

2.4.3. *Hydrogenation of Fatty Acids produced by Oxidation of Paraffinic Hydrocarbons*

The process for the oxidation of paraffinic hydrocarbons, developed in Germany before 1940, is used on an industrial scale in Russia for the manufacture of fatty acids. About 5 – 10 % of these synthetic fatty acids are converted to fatty alcohols. The products are mainly linear, primary alcohols, with 5 – 15 % branched alcohols. An overview is given in [61].

A mixture of paraffins is oxidized above 100 °C in the presence of manganese catalysts. The complex product mixture consists of aldehydes, ketones, esters, carboxylic acids, and other compounds. Since the byproducts cannot be completely removed during further processing and distillation of the carboxylic acids, the uses of fatty alcohol produced by this method are limited. As with the natural fatty acids, hydrogenation is carried out after esterification with methanol or butanol. The suspension hydrogenation process is used (see Suspension Hydrogenation.). The distillation residue contains esters of C_{10} – C_{20} alcohols, 25 % of which are secondary. These alcohols can be obtained by hydrolysis.

2.4.4. *Bashkirov Oxidation*

A variant of paraffinic hydrocarbon oxidation was developed in the 1950s in the Soviet Union by BASHKIROV [1], [3]. The paraffins are oxidized in the presence of boric acid, which scavenges the hydroperoxides that are formed as intermediates. This results in the formation of boric acid esters of secondary alcohols. These esters are relatively stable to heat and oxidation. Hydrolysis leads to a statistical distribution of secondary alcohols in which the hydroxyl function may occupy any position on the carbon chain.

Industrial oxidation is carried out at about 160 °C with a nitrogen – air mixture containing about 3.5 % oxygen [62], [63] (⟶ Alcohols, Aliphatic – Oxidation of Saturated Hydrocarbons). The conversion of paraffins is limited to a maximum of 20 % in order to minimize side reactions. The principle reaction steps are depicted in Figure 7.

Figure 7. Bashkirov oxidation

The process is used in the former Soviet Union and in Japan (Nippon Shokubai). A plant operated by Union Carbide in the United States since 1964 is closed.

2.4.5. *Other Processes*

Fatty alcohols can also be obtained by reaction of α-olefins with hydroperoxides in the presence of transition-metal catalysts, especially molybdenum [65]:

$$R-CH=CH_2 + R-OOH \longrightarrow R-\underset{\diagdown O \diagup}{CH-CH_2} + ROH$$

If *tert*-butyl hydroperoxide is used, the coproduct isobutanol can be readily separated from the epoxide.

After separation of the low molecular mass alcohol and purification, the epoxide is hydrogenolyzed in the presence of a nickel catalyst to form the primary alcohol. About 10 – 15 % of the secondary alcohol and 2 % paraffin are obtained as byproducts [66].

Mixtures of linear, primary alcohols with average molecular masses between 400 and 700 (corresponding to a chain length of 30 – 50 carbon atoms) are marketed under the trade name Unilin [67]. The hydrocarbon content of these mixtures is about 20 %. Ethylene oligomers are oxidized to produce oxygen-containing products on an industrial scale [68].

1-Triacontanol, which does not occur in the common natural raw materials and is produced only in minute quantities in petrochemical processes such as the Alfol process, is of interest because of its ability to stimulate plant growth [69]. Several research groups investigated synthetic pathways based on cheap raw materials [70-75].

2.5. Uses

Fatty alcohols are mainly employed as intermediates. In Western Europe, only 5 % are used directly and ca. 95 % in the form of derivatives [76].

Surfactants. The amphiphilic character of fatty alcohols, which results from the combination of a nonpolar, lipophilic carbon chain with a polar, hydrophilic hydroxyl group, confers surface activity upon these compounds. Surfactants account for 70 – 75 % of fatty alcohol production [77].

Due to the their amphiphilic properties fatty alcohols orient themselves at phase interfaces and can therefore be used in emulsions and microemulsions. In cosmetic emulsions (creams, lotions) the main function of the fatty alcohols is to provide consistency, in technical emulsions they are used as cosurfactants and solution aids.

If the hydroxyl group of the fatty alcohols is replaced by other, larger hydrophilic groups, the polar character is enhanced and surfactants are obtained [4]. The most important surfactants derived from fatty alcohols are described in the following (see also ⟶ Laundry Detergents, ⟶ Surfactants).

Alkyl polyglycol ethers, fatty alcohol polyglycol ethers, fatty alcohol ethoxylates, $RCH_2(OCH_2CH_2)_nOH$, were the first nonionic surfactants produced on an industrial scale. They are synthesized in a base-catalyzed reaction. Fatty alcohol-alkylene oxide adducts, which are produced in a base-catalyzed reaction of fatty alcohols, ethylene oxide, and propylene oxide, are low-foaming surfactants.

Alkyl sulfates, fatty alcohol sulfates, belong to the group of anionic surfactants and are the longest known synthetic surfactants. In order to synthesize this class of compounds, fatty alcohols are treated with sulfur trioxide, chlorosulfuric acid, oleum, or sulfuric acid. The resulting semiesters are subsequently neutralized with alkali, mostly aqueous NaOH.

Alkyl polyglycol ether sulfates, fatty alcohol ether sulfates, also belong to the group of anionic surfactants. They are produced by reaction of fatty alcohols with ethylene oxide and the resulting adducts are then treated with sulfur trioxide or chlorosulfuric acid. The subsequent neutralization is carried out with caustic soda, ammonia, or ethanolamine.

Alkyl methylammonium chlorides belong to the group of cationic surfactants and are produced using fatty alcohols especially in the range of C_{16-18}.

Alkylpolyglycosides (APG) are prepared from fatty alcohols and sugars following various procedures. They have good skin compatibility and, if necessary, can be manufactured from renewable raw materials only. However, high production costs are usually a limiting factor for their application.

Other Uses. In addition, the polar character of the fatty alcohols allows their use as lubricants. Esters of fatty alcohols with fatty acids, the so-called wax esters, e.g., as lubricants in polymer processing and as raw materials for waxes and creams in technical applications. Esters are used also in cosmetic applications, but here usually liquid products on the basis of unsaturated fatty alcohols and/or fatty acids are preferred.

Acrylic and methacrylic acid esters of fatty alcohols are precursors of polymethacrylates, which are utilized as flow enhancer and viscosity index improvers in oils. Fumaric acid esters have similar applications. Esters of adipic, acelaic, sebacic, trimellitic, citric, and phthalic acid are used as plasticizers for PVC. The various specific applications of specialty plasticizers are based on their chemical structure, their high cold flexibility, compatibility, high thermostability, high aging stability, and low fogging-values in the finished product. Each of the mentioned esters offers special chemical and physical properties for the different application areas.

A further high volume application is in the area of fragrances and flavors. Aldehydes, esters, or alkyl groups on the basis of fatty alcohols are sometimes incorporated into more complex molecules like cinnamon aldehyde. Important for this application are high-purity single cuts which can be processed into these products without any loss in quality.

Alcohols with a chain length of C_{8-10} are used as so-called tobacco sucker control agents in the cultivation of tobacco.

Especially fatty alcohols with chain lengths $\geq C_{18}$ — either in an emulsified form or as derivatives — are suitable for protection of water reservoirs against evaporation during dry seasons. If fatty alcohols are emulsified with interface-active substances, the resulting emulsion can be applied to the water surfaces. The layer, which is formed fast and easily on the

water surface, prohibits the evaporation and therefore protects the water reserves. Field tests in Europe and in Africa have proved the effectiveness. The evaporation can be reduced to up to 50 %.

The same higher fatty alcohols can also be used as defoamer systems for papers to be produced in modern, fast operating paper machines. Products on the basis of fatty alcohols show the following advantages compared to silicon-based defoamers: high effectiveness, good biodegradability, good drainage and deaeration, water recycling, and high cost effectiveness. Each paper quality and each production facility demands different defoamer qualities, which contain emulsifiers and additives in addition to the alcohol.

[Top of Page]

3. Unsaturated Fatty Alcohols

Unsaturated fatty alcohols are special products and can only be obtained from natural sources; petrochemical processes for their manufacture do not exist. Unsaturated fatty alcohols contain at least one olefinic group in addition to the hydroxyl function. Therefore they can react both as alcohols and as olefins. The physical properties of the most important unsaturated fatty alcohols are listed in Table 4. The melting points are below those of the corresponding saturated alcohols and are influenced by the configuration of the double bond.

Table 4. Physical and chemical properties of primary unsaturated fatty alcohols

IUPAC name	Common name	CAS registry number	Molecular formula	M_r	Hydroxyl number	Iodine number	*mp*, °C	*bp*, °C (*p*, kPa)	Density, g/cm^3 (*t*, °C)	Refractive index (*t*, °C)

Production. The first large-scale hydrogenation plant (Henkel) went into operation in the late 1950s. Previously, unsaturated fatty alcohols could be obtained only by hydrolysis of whale oil (Section Hydrolysis of Wax Esters) or by the Bouveault – Blanc reduction (Section Reduction of Wax Esters with Sodium).

Today, a broad range of raw materials based on animal or vegetable fats and oils are available. Both market factors and the degree of unsaturation (iodine number) required in the final product influence the selection.

For products with iodine numbers around 50, cheap beef tallow or vegetable raw materials are available. Products with iodine numbers of 80 – 100 can be produced from technical oleic acid (animal or vegetable based). Polyunsaturated products are undesirable as they tend to autoxidation. For special applications products with higher iodine numbers (> 110) based on sunflower or soybean oils are produced. Unsaturated alcohols with iodine numbers > 150 are produced, e.g., from linseed oil.

The hydrogenation processes described in Section Hydrogenation Processes are suitable for the large-scale production of unsaturated fatty alcohols. The fixed-bed processes are preferred because of the mild reaction conditions. In suspension hydrogenation, the prolonged contact between fatty alcohol and catalyst results in side reactions such as saturation of the double bond and formation of trans isomers, which leads to a higher solidification point and, hence, loss of quality. With polyunsaturated fatty acids, the formation of conjugated double bonds cannot be completely prevented.

Hydrogenation is generally carried out at 250 – 280 °C and a pressure of 20 – 25 MPa. Catalysts include zinc oxide in conjunction with aluminum oxide, chromium oxide, or iron oxide, and possibly other promoters [84-89]; copper chromite whose activity has been reduced by the addition of cadmium compounds; and cadmium oxide on an alumina carrier [90].

Selective hydrogenation can also be carried out in a homogeneous phase with metallic soaps as catalysts. An overview of early catalyst developments is given in [78]; further references can be found in [79-83]. Patent applications of the 1980s indicate great interest in selective catalysts [91-96].

Unsaturated fatty alcohols are produced in the Federal Republic of Germany (Henkel, Ecogreen) and in Japan (New Japan Chemical).

Uses. Unsaturated fatty alcohols are used in detergents, in cosmetic ointments and creams, as plasticizers and defoamers and in textile and leather processing [23], [97-99]. Oleyl alcohol is also used as an additive in petroleum and lubricating oils.

4. Guerbet Alcohols

Condensation of primary alcohols at 180 – 300 °C in the presence of alkaline condensation agents leads to primary, α-branched dimeric alcohols. The difference in structure between Guerbet and other branched fatty alcohols is shown in Figure 8. The physical and chemical properties of Guerbet alcohols are listed in Table 5.

Figure 8. Examples of different types of branched fatty alcohols

Table 5. Physical and chemical properties of Guerbet alcohols

2-Eicosyl-1-tetracosanol	[73761-81-6]	$C_{44}H_{90}O$	635.22	93		

The condensation reaction was first observed by M. GUERBET [100]. Its mechanism and selection of catalysts has been thoroughly studied [3], [5]. Figure 9 illustrates the reaction mechanism in simplified terms.

Figure 9. Mechanism of the Guerbet reaction

Today this reaction is performed on a technical scale with a worldwide production capacity of several thousand tons per year. The alcohol which is to be dimerized is mixed with an alkaline condensation agent and a hydrogenation/dehydrogenation catalyst and then heated to 180 – 300 °C. The water formed in the reaction is distilled off continuously together with the monomeric alcohol. Since the reaction proceeds faster at higher temperatures, especially the reaction of short-chain monomeric alcohols (C_6 – C_{10} alcohols) is performed under pressure to perform it in a suitable temperature range. However, low-molecular, α-branched dimeric alcohols, e.g., 2-ethyl-1-hexanol, can be produced more economically by other methods (⟶ 2-Ethylhexanol).

Physical Properties. The physicochemical properties of Guerbet alcohols can be summarized as follows [101]:

- Melting point or pour point are considerably lower than those of linear alcohols with the same molecular mass.
- Volatility and vapor pressure are significantly lower than those of linear alcohols with comparable consistency (but lower molecular mass).
- As compared with other liquid unsaturated alcohols the Guerbet alcohols are stable against oxidation and autoxidation.

Uses. Based on these properties Guerbet alcohols in the range of C_{12-36} can be used in the following application areas:

- Cosmetic-pharmaceutical oil components with high stability against autoxidation (rancidity)
- Plasticizers for synthetic resins, e.g., nitrocellulose lacquers (for the production of permanent templates)
- Solvents or solution aids for printing inks and specialty inks
- Lubricant components, e.g., for metal processing oils and fiber preparations
- Chemical intermediates, e.g., for production of branched carboxylic acids
- Starting materials for textile auxiliaries, e.g., esters, sulfates, phosphates, ethersulfates

The Guerbet alcohols C_{32-36}, which can be manufactured from C_{16-18}-alcohols, are used as:

- Esterification components for the manufacture of specialty waxes
- Raw materials for cosmetic stick preparations

5. Bifunctional Fatty Alcohols

Some natural oils which contain double bonds, hydroxyl groups, or other functional groups can be converted into long-chain diols. These are usually α, ω-diols or diols whose hydroxyl groups lie far apart. Table 6 lists physical properties of bifunctional fatty alcohols.

Table 6. Physical and chemical properties of bifunctional fatty alcohols

1,2-Diols can be produced by epoxidation of internal or α-olefins with subsequent hydrolytic cleavage of the epoxide ring (→ Alcohols, Polyhydric).

Dimerization of unsaturated fatty acids such as soybean, linseed, and tallow fatty acid, followed by esterification and catalytic hydrogenation, gives saturated diols [102].

α, ω-unsaturated fatty alcohols can be produced by pyrolysis of castor oil (Atochem) or by metathesis of oleic acid methyl ester [103].

Thermal or catalytic dimerization of unsaturated alcohols yields viscous dimers with complex structure and an average of two hydroxyl groups per molecule [104], [105].

1,12-Octadecanediol, 1,10-decanediol, and 9-octadecene-1,12-diol are obtained from castor oil by transesterification and hydrogenation, or by alkali splitting, esterification, and hydrogenation. α, ω-Diols with high purity can be produced from the corresponding dicarboxylate esters [106], e.g.,

Suberate → 1,8-Octanediol
Sebacate → 1,10-Decanediol
Dodecanedioate → 1,12-Dodecanediol

Sebacic acid is based on castor oil. Nature offers today new plants and new renewable raw materials for different applications by cultivation or genetic engineering.

Bifunctional fatty alcohols are mainly used in the production of polyesters and polyamides and as intermediates.

6. Quality Specifications

Analytical methods defined by DIN [107] and ASTM [108] standards and by the Deutsche Gesellschaft für Fettwissenschaft (DGF) [109] are used for the quality control of fatty alcohols (see Table 7). In addition, analytical methods from the different fatty alcohol suppliers might be used.

Composition of fatty alcohol mixtures is determined by gas chromatography, which can be combined with mass spectrometry. Alcohols from different sources can thus be identified; typical examples are given in Figure 10.

Figure 10. Typical fatty alcohol compositions obtained by different processes

(Blue = *n*-alcohols; Violet = isoalcohols; Yellow = unsaturated alcohols; *L* = linearity)

* DGF = Deutsche Gesellschaft für Fettwissenschaft.

Linearity *L* is defined as the percentage of normal alcohols present in the mixture:

$$L = \frac{n - \text{alcohol}}{n - \text{alcohol} + \text{isoalcohol}} \times 100$$

Coconut alcohol gives very few impurity peaks. It contains < 0.1 % *n*-tridecanol and varying amounts of *n*-alkanes, depending on the hydrogenation process.

Tallow alcohol contains up to 2 % isomeric pentadecanols (isopentadecanol, anteisopentadecanol, and *n*-pentadecanol) and *n*-hexadecane, and up to 4 % isomeric heptadecanols (isoheptadecanol, anteisoheptadecanol, and *n*-heptadecanol) and *n*-octadecane.

Ziegler alcohols (Alfol and Epal alcohols) are primary, straight-chain alcohols with an even carbon number. Gas chromatography shows up to 1 % impurities, consisting of numerous even-numbered, isomeric fatty alcohols.

Oxo alcohols from statistical, cracked olefins or from paraffin dehydrogenation by the Pacol process or SHOP olefins contain

a large number of isomers that cannot be completely separated, even in the most efficient capillary columns. Both odd- and even-numbered isoalcohols occur. Oxo alcohol mixtures can be identified by spectroscopic determination of the degree of branching, i.e., the ratio of *n*-alcohols to isoalcohols, which depends on the production process and the raw materials used.

Fatty acids obtained by *oxidation of paraffinic hydrocarbons* yield even- and odd-numbered primary alcohols with a low degree of branching. Branched alkanes present in the original paraffins are lost by oxidative degradation.

The boric acid-catalyzed process (Bashkirov oxidation) yields secondary alcohols with a statistical distribution of isomers.

Guerbet alcohols are primary, α-branched fatty alcohols with two straight-chain alkyl groups of approximately equal length.

[Top of Page]

7. Storage and Transportation

During production, processing, and storage, fatty alcohols are handled as liquids. Fatty alcohols starting from $C_{12}OH$ solidify at ambient temperatures. Products with a melting point above 40 °C can therefore be transferred to, stored, and handled as flakes or pastilles.

Fatty alcohols are sensitive to oxidation and should be stored under an inert gas; the temperature should not be higher than 20 °C above the melting point. Low-pressure steam or warm water are recommended for heating. Water increases stability to autoxidation; as little as 0.1 % has a stabilizing effect. The use of antioxidants depends on further processing and quality requirements.

Stainless steel or an Al – Mg – Mn alloy (DIN 1725/1745) is used as container material; ordinary steel should have a zinc silicate coating, e.g., Dimetcote. Pumps, valves, and pipes exposed to the product should be made of stainless steel.

Fatty alcohols are considered as flammable materials and are classified according to properties such as flash point and boiling point. Their transport is governed by national and international regulations dealing with volatile and combustible materials.

[Top of Page]

8. Economic Aspects

The economic significance of fatty alcohols is reflected by the worldwide installed production capacities of ca. 2.4×10^6 t/a in 2004, which will increase to ca. 2.8×10^6 t/a by the year 2007. Table 8 shows these production capacities categorized by volume, location and raw materials. In summary, ca. 50 % of the fatty alcohols are produced from natural raw materials, but the split per geographical region is different from continent to continent and will shift to 60 % in favor of natural-based fatty alcohols by 2008. Worldwide production and consumption are estimated at $1.8 – 1.9 \times 10^6$ t/a for 2004 with a yearly increase of 2 – 3 %. In Europe only ca. 5 % of this volume is used directly as fatty alcohols. A share of 70 – 75 % is used in surfactants exclusively [76], [77], [110-114].

Table 8. Estimated production capacities for fatty alcohols in 2005, 10^3 t

Continent	Natural alcohols, ≥ C_{10}	Synthetic alcohols, ≥ C_{11}	Total
USA	190	560	750
Europe/South Africa	395	529	924
Asia	651	142	793
Total	1236	1231	2467

In the United States the synthetic fatty alcohol capacities predominate with ca. 70 % share of the total capacity. The largest producers of synthetic alcohols are Shell (SHOP/oxo process), and Sasol North America (Ziegler/Alfol process). Natural fatty alcohols are produced by Procter & Gamble and Cognis (formerly Henkel).

In Europe/South Africa, ca. 40 % of the production capacity is based on natural raw materials. The largest manufacturer is the Sasol Group, exploiting all three technologies, i.e., Ziegler, oxo and natural production processes. Other European manufacturers, such as BASF, ICI, Exxon, and Shell, predominantly use the oxo process. As the second largest Western European manufacturer for fatty alcohols, Cognis, produces exclusively from natural raw materials using high pressure hydrogenation processes.

In the Far East the share of production capacities from natural raw materials is ca. 80 %. This share will further increase by planned additional capacities of about 600 000 t by 2008. The currently largest manufacturers of natural fatty alcohols are Ecogreen, Sawit Mas, and Kao Soap Corp. Synthetic fatty alcohols are manufactured by the oxo process, e.g., by Mitsubishi Chemical, Mitsubishi Petrochemical and Fushun, or by the Ziegler process, used in Jilin.

In Eastern Europe fatty alcohols are manufactured predominantly on the basis of the paraffin oxidation process.

Considering the existing production capacities and based on the announced capacity increases, assuming an estimated yearly increase of the fatty alcohol demand of 2 % to 3 %, ca. 80 % of the capacities will be utilized through the year 2005 [76], [77], [116], [118]. The planned new capacities will be based on fats and oils and on petrochemical or Fischer – Tropsch raw materials, respectively.

The capacity utilization of each production unit depends on the overall economic development, the product mix and the prices for the used raw materials. Figure 11 shows the differences in price for raw materials based on crude oil, fats, and oils.

Figure 11. Price development of raw materials used for the production of fatty alcohols

While until 1973 crude oil based, synthetic fatty alcohol production units had considerable advantages, this picture changed significantly due to the price increases for crude oil in 1973 – 1974 and 1979 – 1980 and subsequently for secondary products such as naphtha, paraffins, and ethylene. On the long run the price increase rate for fats and oils was considered to be lower than for crude oil [76], [77], [115], [116], [120-127], leading to an expansion of the natural production capacities. In the beginning of 1999 the price for crude oil was again nearly as low as the price in 1974. Therefore, fatty alcohols on the basis of petrochemical raw materials had a cost advantage over natural-based fatty alcohols. This changed again in the second half of 1999, whereas in 2005 the natural-based products enjoy the advantage of high crude oil prices again. The period 1995 – 2005 was a decade of change [119]. Some units were shut down or reinstalled at other places, and larger plants were build to take advantage of economy of scale. Pants with a size of 100 000 t/a are now regarded as standard.

The long-term estimate was based on an increase in crop yields for fats and oils, new hybrids of oil plants, a wider geographical distribution of their cultivation areas, and the renewable character of these raw materials in contrast to crude oil. All of this guaranteed a reliable supply. Therefore, the ratio of the production capacities of synthetic to natural fatty alcohols changed in favor of natural products (2005). In spite of production increases for coconut oils, increased utilization of palm kernel and babassu oils, and the new hybrids of C_{12}-rich oils like cuphea varieties, natural products are mainly limited to the C_{16} – C_{18} range (90 % of all products) [128]. Synthetic alcohols, however, show their strength especially in the C_{12} – C_{15} range, which plays an important role in surfactant applications. Therefore, the C_{16} – C_{18} C-chain range is predominantly based on natural, the C_{12} – C_{15} range on petrochemical based raw materials. However, due to logistical, economical and political reasons, overlapping and reversals can occur [76], [115], [116].

[Top of Page]

9. Ecotoxicology and Toxicology

The following toxicological characterization covers alcohols with C-chain lengths from C_6 to C_{24}. Besides data regarding the acute toxicity (after single intake of the substance) and regarding local effects (skin- and mucous membrane irritation, data on sensitization effects), especially data regarding the toxicity after repeated intake of small amounts of a substance need to be taken into account for the toxicological characterization. This is especially valid for substances which have virtually no acute toxicity as e.g. fatty alcohols. Questions regarding a possible carcinogenic effect or regarding possible reproduction damage or teratogenic effects are the main focus point today when the toxicological properties of chemical substances are assessed.

For the assessment of the properties of fatty alcohols Condea data and data from scientific publications were used. Here especially the IUCLID-data [129] were consulted, which were compiled by the manufacturers according to the ECAltstoffverordnung (EEC 793/93).

9.1. Ecotoxicology and Environmental Aspects

Linear fatty alcohols are in general easily biodegradable. The biological degradation of secondary fatty alcohols proceeds slightly slower, however, the decomposition rates in standardized lab tests are comparatively high. For the assessment of the

data it has to be considered that the solubility of fatty alcohols in water decreases with increasing C-chain length. Therefore, the alcohols are present only in an extremely low concentration in aquatic environments. Effects, which are detected in various test systems, often have to be regarded as secondary effects caused by undissolved, finely dispersed substance particles, and therefore have to be distinguished from “real” substance effects.

For aquatic organisms fatty alcohols possess only moderate *acute toxicity*. In general, in the concentration range of their water solubility no toxic effects are observed. However, a number of studies was performed with concentrations which are considerably above the water solubility. The observed toxic effects can also be attributed to the aforementioned secondary effects. The available data for the *chronic toxicity* neither indicate a special toxicological potential of fatty alcohols. Dodecanol shows a more distinct toxicity in the studies. However, this toxicity cannot unmistakably be attributed to a direct substance effect, but can possibly be induced by physical effects as well. A complete separation of the aqueous solution from undissolved but finely dispersed dodecanol is virtually impossible. Therefore, a rest of undissolved dodecanol always remains in the water.

9.2. Toxicology

Linear fatty alcohols are predominantly metabolized by oxidation. The resulting fatty acids can be subsequently integrated into the fatty acid metabolism. A further metabolic reaction is conjugation of the fatty alcohols with glucuronic acid and subsequent excretion.

Fatty alcohols possess virtually no *acute toxicity* after oral intake or after exposure to the skin. Especially fatty alcohols with a shorter C-chain length irritate the skin in higher concentrations, in animal tests eye irritations were observed as well. The irritating effect decreases with increasing C-chain length. In studies with volunteers some fatty alcohols show a considerably lower skin irritating effect. This has, at least in part, to be attributed to the different test conditions of studies with volunteers as compared with animal experiments. The available data and the chemical structure of fatty alcohols do not indicate a sensitizing potential of fatty alcohols. From today's point of view even after long-term intake of the typical linear fatty alcohols, substance induced damage is not to be expected. The available data show that fatty alcohols do not possess *genotoxicity*, which is not to be expected anyway on grounds of their chemical structure. Valid data regarding a *carcinogenic effect* are not available. But, based on structure-effect considerations, it can be assumed that fatty alcohols do not have a carcinogenic potential.

For some of the fatty alcohols at least guidance data on *reproduction toxicity* are available. These data show that under the study conditions fatty alcohols neither reduced the fertility nor had an embryo or fetotoxic effect.

In Table 10 data on the toxicity of fatty acids after short-term exposure are listed. Table 11 summarizes data on the acute toxicity to aquatic organisms and degradability data [129-134].

Table 10. Acute toxicity (oral and dermal), skin Irritation, eye Irritation, and sensitization of fatty alcohols (data from animal experiments)

Substance	LD_{50} (oral)	LD_{50} (dermal)	Skin Irritation	Eye Irritation	Sensitization
1-Hexanol	3100 – 5000 mg/kg (rat)	1500 – >5000 mg/kg (rabbit)	moderately irritant	irritant	no sensitization

1. Introduction

Felt (nonwoven) is defined as a material made entirely from mechanically consolidated fibers (DIN 61 205).

Pressed felts (wool and hair felts) are materials, composed either of fibers that can be felted or of a mixture of these and other fibers. These nonwoven fabrics are consolidated by the utilization of moisture, heat, pressure, and mechanical work (felting and, if necessary, pressing).

Needled felts are materials made from fibers that are consolidated by using a large number of needles. The needles alternately penetrate and are withdrawn from the fibers in a process called needling.

Nonwovens (→ Nonwoven Fabrics) are distinguished in DIN 61 210 from needled felts because they are consolidated by the following different methods:

1) by use of a binding agent
2) by partially dissolving the fibers
3) by melting the fibers
4) by shrinking the fibers under the influence of heat and/or a swelling agent
5) by the action of liquid jets
6) by needling and subsequent consolidation, using methods 1 to 4 [1]

The felting of wool and animal hair was discovered in ancient times. Felt caps, 3500 years old, were found in the megalithic graves of Jutland. The Chinese referred to felt as far back as 2300 B.C. [2].

Figure 1. Scanning electron micrograph (× 3500) of a Merino wool fiber

2. Felting Process

The felting process ist still not completely understood [3], [4]. The felting ability of wool fibers depends primarily on the scales on their surface (Fig. 1) and on their elastic properties (see also → Wool). The scales of any one fiber all point in the same direction, thereby creating a directional frictional effect that allows the fibers to move more easily in the direction of their roots when force is applied. Only fibers with scales can be felted. During felting and fulling of fibrous webs (batt), the individual fibers are pressed together, forced to move against one another, and become mutually intertwined. Ends or parts of fibers that are not interlocked escape into the interspaces in the felt. On removing the applied compressing force (stress relief), the fibers try to spring back

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a10_297

into their original stress-free positions. However, friction prevents complete stress relief. The original position and form of each fiber is permanently changed at the end of felting and fulling, and the fibers are firmly interlocked.

3. Pressed Felts

3.1. Raw Materials

Wool and/or other animal hair are the basic raw materials for the production of pressed felts (wool felts, hair felts, and hair – wool felts). Only these fibers possess the natural felting power that enables the fibrous web made from the carded fibers to be consolidated by using moist heat pressure, and mechanical work. Other fibers that cannot be felted (cellulose fibers, synthetic fibers, cotton, etc.) can be added to obtain special effects, to produce felts with specific properties, or to reduce costs.

Hair – wool felts are produced from a mixture of wool and animal hair (preferentially hair from cattle, calves, or goats). Since the fulling power of hair is lower than that of wool, the felted, semifinished product is soaked in hot, dilute sulfuric acid before fulling.

Bating. Hat felts contain wool, rabbit fur, or hare fur (velour hats). The animal fur first has to be softened to improve its fulling power by a process known as bating. The fur is usually exposed to a mineral acid – hydrogen peroxide solution (bate). Poisonous mercury bates are employed only in the production of velour from hare fur.

In bating machines, only the ends of the hairs are exposed to the bate making them softer, more pliable, and more resilient. As a result, they can intertwine more easily when the untreated hair shafts move in the direction of their roots during felting and fulling. Bating also increases the frictional coefficient of the animal hairs, and thus improves their mutual adhesion [5].

3.2. Production

The production of pressed felts is summarized schematically in Figure 2 (cf. [6]).

3.2.1. Batt Production

The raw fiber material is fed into one or more carding willows either in pneumatic mixing plants or multiple mixers. The fiber flocks are loosened (opened), and uniformly blended during repeated passage through the machine. Addition of carding oil makes the fibers pliable for further processing. The loosened fibers are then fed in batches into a carding machine via a weigh feeder which may be electronically controlled or via a volumetrically controlled hopper. The carding machine separates the fiber flocks into their individual fibers. Different card sets are available, depending on the raw material, and the required quality and properties of the resulting batt. The fibers leaving the carding machine are longitudinally oriented in the form of a web which has a mass of $10-20\,g/m^2$. The carded web is laid in several layers on the 60 – 70-m long, continuous cloth belt of a batt frame (Fig. 3) to produce a predetermined thickness or mass of batt. The resulting batt is subsequently rolled up.

In the continuous production of "cross-laid" or "cross-lapped" batt, carding is followed by the use of a cross lapper instead of a batt frame. The cross lapper picks up the carded web and deposits it at alternating angles of about 45° (i.e., in a zig-zag pattern) across a conveyor belt (→ Nonwoven Fabrics) so that the fibers are aligned crossways. The cross-lapped batt can be laid onto another oriented web and its mass can be changed by stretching. Ideally, a multidirectional web is obtained whose tensile strengths in the lateral and longitudinal directions are the same [7].

Both methods yield batt in roll form; this is the starting material for the production of piece felts and formed felts.

3.2.2. Piece Felts

Felting. The batts used to produce piece felts are laid singly or on top of one another, depending on the thickness or mass desired in the finished product. The layers of batt are then conveyed between damp cotton cloths and fed into a plate hardener or roller hardening machine. Before entering the felting aggregate (vibrating plates or felting rollers), the batts pass over a

Figure 2. Production of piece and formed felts

steaming plate, where they are moistened and heated by the steam that passes through them.

The circular vibrator motion of the felting plates in the discontinuously operating *plate hardener* (Fig. 4) coupled with the action of moisture, heat, and pressure consolidate and felt the fibers.

Figure 3. Schematic of a batt frame

Figure 4. Plate hardener
The hardening plates are shown lifted for transporting the felt, they are lowered during felting.

Figure 5. Roller hardening machine
a) Axially vibrating rollers: b) Heated rollers; c) Conveyor belt; d) Cotton cloth

Figure 6. Pilgrim Step roller fulling machine
a) Steam heating; b) Outlet table; c) Fulling rollers; d) Sprinkling device; e) Inlet table

In the continuous *roller hardening machine*, the cotton cloths and the batt pass through two horizontal rows of rollers, one row being above the other (Fig. 5). The lower rollers are made of stainless steel and are heated, while the upper rollers are coated with plastic and vibrate axially. The batt is pressed between each pair of rollers and subjected to their vibrating action. The pressure is released between two consecutive pairs of rollers. The batt is thus consolidated and felted [8].

Fulling. The production of felts with higher densities involves the use of a procedure called fulling. In this process, the material is further felted by kneading, hammering, and pounding, often with the addition of fulling media. Some felts need no further consolidation by fulling, however. Felts used for upholstery and quilts, for example, are merely dried and, if necessary, finished after felting. Lighter piece felts and industrial felts, which may not need to be processed in a kicker mill, are fulled on a roller fulling machine or a Pilgrim Step roller fulling machine.

In a roller fulling machine (shown schematically in Fig. 2, fulling of piece felts), the felt passes between two horizontal rows of 15, 21, or 24 rollers, one row being above the other. The rollers are made of steel and are covered with rubber. For light felts, lower rollers with a diameter of 90 mm are used, but for processing heavier felts, the diameter of the lower rollers must be increased to 120 mm. Only the lower rollers are powered and their speed decreases from roller to roller, which causes the material to "pile up" into folds in the direction of transport. The diameter of the upper rollers is ca. 10 mm less than that of the lower rollers mounted exactly below them. The upper rollers have spring bearings and turn on contact with the folds of material produced by the lower rollers. At high running speed, the upper rollers hammer and beat the material as it passes through the machine [9].

In the *Pilgrim Step roller fulling machine* (Fig. 6), the felt is again transported on a conveyor belt between two horizontal rows of rollers. The rollers work in Pilgrim Step, i.e., they swing forward and backward, the backward

movement being shorter than the forward movement. Thick folded layers of felt are thus formed, which are intensively kneaded and processed as they pass through the machine.

Kicker mills (also known as hammer fulling machines) are used for fulling heavier piece felts with a thickness of several millimeters; they are indispensable for the processing of formed felts, such as disks, sheets, or blocks. They are equipped with one to four hammers (Fig. 7).

Figure 7. Kicker mill
a) Felt sheet; b) Filling material; c) Trough; d) Hammers (only two of the three hammers are shown)

The type of fulling aid employed depends on the felt quality, mass, bulk density, and the fulling method (machine). Steam or warm water is often sufficient for fulling light felts with a roller fulling machine or a Pilgrim Step roller fulling machine. Fulling with a kicker mill requires the addition of fulling aids such as sulfuric acid, soaps, anionic fatty acid condensation products, or nonionic compounds based on high molecular mass ethoxylated alcohols.

Final Treatment. The wool used for felt production often contains marking ink (pitch marks), which is manually treated with pitch solvents before washing. These solvents should then be washed off along with the lubricants, fulling media, wool grease, and dirt. Continuous cycle washing machines are used, primarily because they are less expensive and save water.

The washed, natural-colored felt can be dried and finished. However, lighter felts are generally dyed by piece dyeing in high-temperature beam dyeing machines, where the felt is wound on perforated drums, or on winch becks in the form of ropes.

Squeeze foulards or centrifuges are employed to remove water. The felt is then stretched and dried with warm air on drying frames (single layer or multilayer tenters). Finishing foulards can also be used prior to the drying tenters. The felt is held in place by means of chains studded with needles or tenter clips as it passes through the frame. Advancing or lagging results in shrinkage or stretching and, thus, determines the dimensions of the felt. Felts used for clothing, decorative purposes, and toys are subjected to finishing, which involves shearing, steaming, decatizing, and/or pressing. Felts may be given other special finishing treatments, depending on the purpose for which they are to be used; they may, for example, be stiffened, softened, flameproofed, or mothproofed.

3.2.3. Formed Felts

In the production of formed felts (summarized in Fig. 2), the carded fibrous web is roughly formed into a defined shape (round, square, or rectangular) and is then built up by crosslaying successive layers. The preformed web is conveyed between cloths over a steaming plate and steamed before being felted in a plate hardener. Felting in the hardener may take several minutes, depending on the thickness of the felt. The formed felts are then treated with dilute sulfuric acid and are either partially fulled on a Pilgrim Step roller fulling machine or completely fulled to yield a specific density of 0.40 – 0.44 g/cm^3. A kicker mill must be used if a high degree of hardness is required (greater than F 4 as specified in DIN 61 200). During fulling the felt must be constantly kept moist and warm with hot water or with fulling liquor, i.e., hot dilute sulfuric acid. The felt is subsequently deacidified in neutralization tubs and, if necessary, leveled in a Pilgrim Step process. It is then centrifuged to reduce its moisture content to ca. 60 % and dried in a drying room until the residual moisture content is

5 – 10 %. The felt disks, sheets, and blocks are then pressed and their surfaces are sanded. This material may be punched, cut, drilled, molded, or machined to provide a large variety of items.

Hat felt must be very carefully fulled. Only hard, compact felts should be used for making hats; these felts are produced as described in Section 3.2.1 by blending, opening, and cleaning the wool or bated hair. The resulting material is subsequently formed on a cone, and is then felted and fulled to a specific size on machines specially constructed for hat production. The form thus obtained is finally dyed, stiffened, formed, prepared, and decorated.

3.3. Properties

The properties of felt are determined primarily by the choice of raw materials and by the manufacturing method used. Felts can be as soft and pliable as fabrics, flexible/resilient, or even hard. Bulk densities of up to 0.80 g/cm^3 have been attained under optimal conditions. Top-quality products with a density of 1.0 g/cm^3 can be made in special cases by adding thermoplastic fibers and further pressing.

Felt displays the following special properties: elasticity, porosity (high pore volume), tensile strength combined with extensibility; high, density-dependent compressibility and recovery; thermal insulation (heat retention) and shock (vibration) and sound absorption; formability; permeability to air and moisture ("breathing," moisture exchange); absorptive capacity; and uniform dyeing. The properties of wool felt are not significantly altered by long-term exposure to lubricants and organic solvents. A low concentration of an inorganic acid, such as sulfuric or hydrochloric acid, does not have an adverse effect on wool felts, but a strong alkaline solution does. Unlike some other industrial materials, wool felts are affected very little by atmospheric factors, such as moisture, heat, cold, sun, and ozone. Felt is unchanged by temperatures from -50 to 100 °C. Two of the most important features of wool felt as a mechanical and industrial material are that it is durable and relatively maintenance-free.

3.4. Uses

Felts are sold as piece felts in lengths (rolled or doubled) or as formed felts (blocks, sheets, disks) and processed as such into felt goods. They are used industrially in the manufacture of machines, equipment, and automotive vehicles. The natural properties of felt are exploited for a wide range of applications, e.g., for dust and oil seals, oil wicks, roller coverings, air and liquid filters, polishing and buffing wheels, self-adhesive insulating tapes, prepunched insulating components, sound proofing, shock absorption linings, pads, piano felts, and orthopedic and surgical felts [10].

3.5. Testing

The most imortant tests performed on industrial felts are the determination of their *hardness* characterized by the *bulk density* ϱ_{RX} in g/cm^3 and their *thickness*. Felt hardness classes, as defined in DIN 61 200, are given in Table 1. Felt hardness is directly related to the pore volume, compressibility, and elasticity. The bulk density, according to DIN 53 855 and ASTM D461-59, is calculated from the mass and the volume of the felt [11].

Table 1. Hardness classification of felts (DIN 61200)

Bulk density ϱ_{Rx}, g/cm^3	Felt hardness
0.10 – 0.16	soft
0.18 – 0.30	intermediate
0.32 – 0.48	compact
0.52 – 0.68	hard

Standard procedures for testing felt thickness are described in DIN 53 855 and largely correspond to those stipulated in ISO 4603 and ISO 5084. The *standard thickness* of wool felt is measured on a circular testing area of 10 cm^2. A testing pressure of 5 cN/cm^2 must be applied to felt with a bulk density < 0.14 g/cm^3, and a pressure of 25 cN/cm^2 to felts with a bulk density > 0.14 g/cm^3. For smaller testing areas ($<$10 cm^2), the testing pressure must be reduced proportionately.

The *relative compressibility* ZR_{x} is defined in DIN 53 855 as:

$$ZR_{\mathrm{x}} = \frac{a_{\mathrm{x}} - a_{10\mathrm{x}}}{a_{\mathrm{x}}} 100\,\%$$

where a_x is the standard thickness of the felt determined by using the normal testing pressure (average of more than three determinations) and a_{10x} is the thickness when a 10-fold higher pressure is applied.

The *pore content* V_{px} is calculated from the density of the fibers, ϱ_N, and the bulk density, ϱ_{Rx}:

$$V_{px} = \frac{\varrho_N - \varrho_{Rx}}{\varrho_N} 100\,\%$$

In the case of mixed felts, the density of the fibers, ϱ_N, is obtained from the densities of the components of the mixture.

Further tests can be conducted for special purposes, some being performed in both longitudinal and lateral directions. These tests are described in DIN 61 206 and ASTM D461-77 and include the determination of the following properties: tensile strength and elongation at break, rupture strength, washing or ironing shrinkage, wool content, length and width, basic mass (mass related to area), air permeability, abrasion loss, pH value, residual fat content, longitudinal resistance to fluid flow, degree of sound absorption, thermal conductivity, and fiber damage based on the measurement of the alkali solubility of wool. Other properties are oil absorption, intrinsic vibration frequency, vibration damping, and heat resistance. The vibration test can be used to determine the felting capacity of wool [12]. Alkali and acid solubility tests can also be employed in the case of bated rabbit and hare fur [13].

4. Needled Felts

The use of needled felts for industrial purposes dates from the 1870s. The technique of needling creates feltlike structures from fibers that are otherwise incapable of being felted by means of numerous barbed needles that vertically penetrate and compress the fibers.

The appearance in the 1950s of new synthetic fibers with novel properties stimulated further development of the needling technique. New, efficient needling machines, in combination with improved felting needles, led to the development of products with new properties that could not be obtained by other methods [14].

4.1. Production

The choice of raw materials depends on the demands made on the needled felts and, thus, on the manifold uses of the finished product. Synthetic fibers consisting of natural and synthetic polymers and inorganic fibers are preferred, but carbon fibers can also be employed. Fibers based on aromatic polyamides (e.g., Nomex, Kevlar) and on polytetrafluoroethylene (e.g., Teflon) are of considerable industrial importance. Needled floor coverings are made chiefly from polyamide and polypropylene fibers. Products used for insulation and upholstery are made from low-grade fibrous material or from recycled natural fibers, cellulose, or synthetic fibers.

The raw material is first loosened (opened) and blended in a willower. A lubricant or antistatic agent can be added at this stage. The fibers are then aerodynamically built up as a multidirectional web. Alternatively, a crosslapped web can be produced on a carding machine and may subsequently be stretched; a multidirectional web can then be obtained with additional equipment.

In the needling machine (Fig. 8), the web fibers pass between two parallel perforated plates and are penetrated by numerous barbed needles. The barbs force the fibers down and, as needling progresses, they become increasingly intertwined thus consolidating the web. The fibers remain locked in their new positions when the needles are withdrawn because the barbs all face in one direction, i.e., toward the needle point. To attain greater compaction and consolidation, several needling machines are usually employed in series. These machines often differ from each other in their needle fittings or in the direction of penetration. The web can be subjected to needling from one side either above or below, or from both sides, either alternately or simultaneously.

In felts required for some industrial uses, the web is needled into a base material made of woven or spunbonded threads, or foil to produce high tensile strength, low stretching, and high resistance to deformation [15].

Mechanical and thermal treatments as well as chemical finishing (singeing, shrinkage, thermofixation, spraying, coating, etc.) produce special effects and influence the dimensions and

physical properties of the felt, such as thickness, porosity, elasticity, and volume. The surface of a needled felt is generally smooth, but the texture can be manipulated to give a velour, looped, or patterned surface [16].

4.2. Properties and Uses

The properties and uses of needled felt products are directly related to the fibrous raw material, to the method of batt formation, and to the needling technique employed. The uniform distribution of fibers combined with an almost uniform density throughout the felt makes needled felts more suitable for filtration than woven or roughened sheet structures. Therefore, needled felt filters have proved to be an efficient medium for commercial air filtration (dust separation, product recovery, and air purification) and for the separation of solids from liquids.

In the paper industry, needled felts that are more than 15 m wide and are made from synthetic fibers have almost completely replaced the conventional woven felts made from wool or asbestos (woven in tubular form as round felts) [17]. Durable floor coverings for living areas are available in a wide variety of colors, surface structures, and patterns. Needled felts are also employed as floor coverings for indoor tennis courts. Other uses include interior decorations, soundproofing in cars, wall coverings, mattress covers, thermal insulation, and shock and sound absorption. A more recent application of needled felts is their use a geotextiles which are modern construction materials used in water and dam construction, land recovery, and other sectors of civil and hydraulic engineering [17].

Ferroalloys

RUDOLF FICHTE, Gesellschaft für Elektrometallurgie mbH, Nürnberg, Federal Republic of Germany

Ferroalloys are master alloys containing elements that are more or less soluble in molten iron and that improve the properties of iron and steel. These alloys usually contain a significant amount of iron [*7439-89-6*]. Ferroalloys have been used for the last 100 years, principally in the production of cast iron and steel [1]. As additives, they give iron and steel improved properties, especially increased tensile strength, wear resistance, and corrosion resistance. These effects come about through one or more of the following: (1) a change in the chemical composition of the steel; (2) the removal or the tying up of harmful impurities such as oxygen, nitrogen, sulfur, or hydrogen; and (3) a change in the nature of the solidification, for example, upon inoculation [2].

Ferroalloys are also used as starting materials in the preparation of chemicals and pure metal; as reducing agents (e.g., the use of ferrosilicon to reduce rich slags); as alloying elements in nonferrous alloys; as starting materials for special products such as amorphous metals. The individual ferroalloys are treated in detail along with the alloys of the non-iron component, e.g., ferroboron is described under → Boron and Boron Alloys. Table 1 lists some commercial ferroalloys. , Chap. 2., Chap. 3.

Over the years, the binary ferroalloys have been modified by the addition of further components. For example, magnesium is regularly added to ferrosilicon, which, when used in cast iron, produces a spheroidal graphite; and manganese or zirconium can be added to calcium–silicon.

Production. Generally, ferroalloys are prepared by direct reduction of oxidic ores or concentrates with carbon (carbothermic), silicon (silicothermic), or aluminum (aluminothermic, closely related to the Goldschmidt reaction; → Aluminothermic Processes). However, roasted ores (e.g., for ferromolybdenum) and pure technical-grade oxides (for ferromolybdenum and ferroboron) are also used as starting materials.

The large-volume ferroalloys – *ferrosilicon, ferromanganese, ferrochromium* – are prepared continuously by carbothermic reduction in large, submerged-arc furnaces. The carbon is provided by coke, and the power supply ranges from 15 to 100 MVA. Ferromanganese is also produced in blast furnaces. Both ferromanganese and ferrochromium, because of their affinity for carbon, contain high concentrations of carbon (7 – 8 wt %). In contrast, ferrosilicon contains little carbon; in fact, the carbon concentration decreases as the silicon concentration is increased, e.g., ferrosilicon containing 25 wt % Si contains 1 wt % C, while that containing 75 wt % Si contains only 0.1 wt % C.

Low-carbon ferromanganese (0.1 – 2 wt % C) or ferrochromium (0.02 – 2 wt % C) is produced in the following way: a silicon-containing alloy, ferrosilicomanganese or ferrosilicochromium, is made by carbothermic reduction of an appropriate ore and quartzite in a submerged-arc furnace. Then this silicon alloy is used for the silicothermic reduction of an appropriate ore in an electric-arc refining furnace. Oxygen is seldom used to reduce the carbon content.

Ferrophosphorus is a byproduct of the carbothermic production of → Phosphorus. *Ferrotungsten* is produced carbothermically in small, high-power electric furnaces. *Ferroboron* is produced from carbon, iron, and boron oxide or boric acid in one- and three-phase electric furnaces. *Zirconium-containing ferrosilicon* is made carbothermically in electric furnaces from zircon ($ZrSiO_4$) or baddeleyite (ZrO_2); ferrosilicon, with either 75 or 90 wt % Si, is added.

Silicothermic reduction, with the addition of some aluminum, is used to prepare *ferromolybdenum* in refractory-lined reaction vessels. The energy released in the reaction is adequate to melt both metal and slag, and the solidified block of ferromolybdenum can be recovered easily. *Ferronickel* is also mainly produced by silicothermic reduction. Aluminothermic reduction is the method of choice for the production of *ferrovanadium.* The starting materials are vanadium(V) oxide, aluminum, and iron turnings,

Ferrosilicozirconium [*51683-55-7*]	35 – 42 Zr	
	ca. 50 Si	

chips, stampings, or nail bits. The reaction is carried out in refractory-lined reaction vessels. The reaction produces enough heat to melt both metal and slag. In fact, inert materials must be added to keep the peak temperature lower. Ferrotitanium and ferroboron are also produced aluminothermically.

The production and use of titanium as a large-volume construction material yields enough scrap for *ferrotitanium* containing ca. 70 wt % Ti to be made by melting iron and titanium scrap together. *Ferrozirconium* containing 80 – 85 wt % Zr is also made by melting metal scrap and iron together. *Ferroselenium* is produced by the exothermic reaction of iron and selenium powders.

The production of ferroalloys is of great economic importance, especially in countries that have the raw materials and the energy supply. Alloy steels constitute an ever growing fraction of total steel production because of their superior properties. As an example of the importance of ferroalloys, an estimated € 0.9×10^9 (ca. \$ 0.8×10^9) of ferroalloys were consumed in 1986 by the steel industry in the Federal Republic of Germany.

Environmental Aspects. During the production of ferroalloys, the emission of undesirable substances into the environment must be kept under control. There are guidelines for this, e.g., see [3]. ""

1. Fundamental Concepts and History

1.1. Fundamental Concepts

Ferroelectrics are materials exhibiting a spontaneous dielectric polarization $\boldsymbol{P}_s$, the direction of which can be reversibly changed by a suitable transient field. The electric dipole moment $\boldsymbol{m} = \boldsymbol{P}_s V$ associated with $\boldsymbol{P}_s$ in a volume V results either from a displacement of the centers of charge relative to each other or from an alignment of existing dipoles, or from a combination of these effects. The two limiting forms of ferroelectrics are classified as displacive type and order – disorder type, respectively. The reversible change in direction of $\boldsymbol{P}_s$ in the case of the displacive type requires the existence of at least two distinct, physically equivalent arrangements of atoms or ions, while in the case of the order – disorder type it requires at least two equivalent orientations of molecular dipoles.

The ferroelectric state is, as a rule, observed only below a temperature T_c, the so-called Curie point, which is characteristic of the particular material. The transition from the paraelectric high-temperature phase, with $\boldsymbol{P}_s = 0$, to the ferroelectric low-temperature phase is invariably associated with a structural phase transition at T_c, in which $\boldsymbol{P}_s$ arises as a result of cooperative displacements in the structural units of the paraelectric phase. If the displacements are viewed as a result of local fields, then the molecular field theory permits calculation of the strength of these fields from the motions and interactions of the structural units.

Since any structural transition that is strictly or approximately second order can be characterized by a suitable chosen order parameter Q, where $-Q- = 0$ for $T > T_c$ and $-Q- > 0$ for $T < T_c$, it is natural in the present case to identify Q as the spontaneous polarization. Ferroelectrics for which this choice proves correct are called proper ferroelectrics. However, there exist cases for which the physical quantity that constitutes a suitable order parameter does not directly result in a polarized state at $T < T_c$. That a ferroelectric phase can nonetheless arise is most readily deduced from the existence of thermodynamic relations of the form $P \propto Q^n$,

where n is called a faintness index. Such ferroelectrics are called improper ferroelectrics. For proper ferroelectrics the spontaneous polarization $\boldsymbol{P}_s$ is the primary order parameter, while for improper ferroelectrics it is a secondary one. Examples are given in Section 1.3.

As an extensive order parameter, Q can be associated with a conjugate intensive variable, a field h, and thus also a susceptibility, $\partial Q/\partial h$.

In the case of proper ferroelectrics these entities are the electric field $\boldsymbol{E}$ and the electric susceptibility $\chi = \partial P/\partial E$,

tensor notation being avoided here in the interest of simplicity. Since stability of a thermodynamic phase requires the reciprocal susceptibilities to be positive definite, a susceptibility can be expected to exhibit singular behavior at a phase transition. Indeed, in the vicinity of the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a10_309

Curie point the static electric susceptibility χ_s is found as a rule to have a temperature dependence in good agreement with the Curie – Weiss law in the form

$$\chi_s - \chi_\infty = \varepsilon_0 C / (T - T_0) \quad (1)$$

where $C \lesseqgtr 0$ for $T \lesseqgtr T_0$ and ε_0 is the permittivity of vacuum.

The Curie temperature T_0 generally is only slightly below the transition temperature T_c. The term χ_∞ represents the practically temperature-independent contribution of those degrees of freedom of the system that do not belong to the order parameter.

A homogeneous ferroelectric possesses a characteristic direction determined by spontaneous polarization. It is therefore polar, noncentrosymmetric, and consequently piezoelectric. Since $\boldsymbol{P}_s$ is in general temperature dependent, ferroelectrics are also pyroelectric. If the temperature of a ferroelectric is lowered from $T > T_c$ to $T < T_c$, as a rule no homogeneous state is produced, even in the case of single crystals. Rather, the crystals exhibit a partitioning into macroscopic domains of homogeneous polarization, analogous to the Weiss domains of ferromagnetics. The form and organization of these domains vary and depend not only on properties of the material but also on lattice defects of the particular sample. The linear dimensions of domains typically lie in the µm to mm range.

Structural phase transitions are in general referred to as ferrodistortive if no change in the periodicity volume occurs during the transition, and specifically are called ferromagnetic, ferroelectric, or ferroelastic if the (primary) order parameter is the magnetization, the polarization, or an elastic deformation, respectively. In addition, however, the transition of a high-temperature to a low-temperature phase of a crystalline substance can also be accompanied by a change in the translational symmetry owing to the increase of the periodicity volume by an integer factor. In particular, structures occur in which the dipole moments in neighboring unit cells are oriented antiparallel to each other. This results in a doubling of the unit cell. Such phases are called antiferrodistortive and, in the electrical case, antiferroelectric.

The nomenclature emphasizes several phenomenological analogies between ferroelectrics and ferromagnetics, which, however, was not a fortunate choice. Occasionally, especially in the Russian literature, the term "Seignette electric" is used. This term, which was in general use until about 1940, relates the phenomenon to the first known ferroelectric, Seignette salt, another name for Rochelle salt. The salt was first prepared by E. SEIGNETTE in La Rochelle, France.

1.2. Early Development

Ferroelectric phenomena were first observed in 1920 by VALASEK [21] in Rochelle salt [*304-59-6*], $KNaC_4H_4O_6 \cdot 4\,H_2O$. In his description, he called attention to the analogy with ferromagnetic phenomena. Besides the dielectric hysteresis in the function $\boldsymbol{P}(\boldsymbol{E})$accompanying reversal of the electric field $\boldsymbol{E}$, VALASEK also noted the extraordinarily high values of components of certain characteristic tensors, such as the dielectric function $e = c + \mathbf{1}$

and the piezoelectric modulus $\mathbf{d}$, within and near the ferroelectric temperature interval, which for Rochelle salt is 255 – 297 K. The existence of a second Curie point, below which the crystal is once again paraelectric, is not common. The second structural transformation, occurring at 255 K, gives rise to a nonpolar low-temperature phase. A satisfactory microscopic theory of the ferroelectric behavior of Rochelle salt has not yet been formulated. The first thermodynamic analysis of ferroelectric transformations was that of MUELLER [22], using Rochelle salt as an example. The central theme of this analysis is a discussion of a suitable thermodynamic potential, which, for a given reference state, is expanded in powers of independent state variables such as dielectric polarization and elastic deformation. Among the most significant results are the relationships between dielectric, elastic, and piezoelectric constants of the material. These relationships allowed the observed anomalies of the latter material constants to be interpreted as consequences of the singular behavior of the dielectric function.

Initially, the ferroelectric effect was viewed as a rare curiosity, so it did not trigger any systematic studies. Not until 1935 was a second substance, potassium dihydrogen phosphate, KH_2PO_4, discovered to be ferroelectric by BUSCH and SCHERRER [23]. This discovery

was important for the further study of ferroelectrics in several respects. One consequence was the prompt discovery that a series of alkali-metal dihydrogen phosphates and arsenates isomorphic with KH_2PO_4 also exhibit ferroelectric behavior [24], thus pointing to a more general significance of these phenomena. Moreover, KH_2PO_4 has a considerably simpler lattice structure than Rochelle salt, so that in 1941 SLATER [25] was able to present a first successful microscopic model for the origin of the ferroelectric effect. Of central importance in this model are ordering processes in the system of hydrogen bridges, which result in the development of dipole moments as a consequence of a relative displacement of the anion and cation lattices.

Since KURCHATOV [26] had assumed in 1933 that orientational processes of water dipoles are the cause of the ferroelectric property of Rochelle salt, a causal relationship between the presence of hydrogen bridges and the occurrence of the ferroelectric effect was now suspected. However, this hypothesis had to be abandoned when, during the years 1945 – 1948, the dielectric anomalies of $BaTiO_3$ were independently discovered in the United States, Russia, and Japan, and WUL and GOLDMANN [27] then observed the ferroelectric transformations of this substance. The extended phenomenological treatment of ferroelectricity of GINZBURG [28] was applied in 1949 – 1954 by DEVONSHIRE [29] to the description of the three successive ferroelectric transitions of $BaTiO_3$. DEVONSHIRE expanded the Gibbs free energy of the cubic high-temperature phase as a polynomial in polarization and deformation and showed that all three ferroelectric phases correspond to minima of the free energy when changes of crystal symmetry were taken into account.

As a structure-sensitive property, ferroelectric behavior was suspected to occur also in related oxides, and indeed in the next years MATTHIAS and collaborators [30], [31] discovered it in $LiTaO_3$, $LiNbO_3$, $KTaO_3$, and $KNbO_3$. These were followed by other titanates and, in 1951, by the first known antiferroelectric, $PbZrO_3$ [32]. In that same year KITTEL [33] published a phenomenological theory of antiferroelectricity.

During the 1950s a succession of other families of ferroelectrics were discovered, confirming the possibility of spontaneous polarization in chemically and crystallographically distinct systems. The following are examples: guanidinium aluminum sulfate hexahydrate [*10199-21-0*] (GASH), $C(NH_2)_3Al(SO_4)_2 \cdot 6\,H_2O$ [34], methylammonium aluminum alum [*15243-18-2*], $CH_3NH_3Al(SO_4)_2 \cdot 12\,H_2O$ [35], ammonium sulfate (AS), $(NH_4)_2SO_4$ [36], triglycine sulfate (TGS), $(NH_2CH_2CO_2H)_3 \cdot H_2SO_4$ [37], and sodium nitrite [*7632-00-0*], $NaNO_2$ [38].

The unusual dielectric and piezoelectric properties of ferroelectric materials soon led to their utilization as ingredients of capacitors and of diverse electroacoustic transducers, such as crystal phonograph pickups and microphones. Unlike the water-soluble and moisture-sensitive crystals, such as potassium dihydrogen phosphate and Rochelle salt, barium titanate is chemically resistant. Moreover, this material is easily manufactured as a polycrystalline ceramic in almost any desired shape. These considerations, as well as the possibility of varying the properties of the material over a wide range by suitable doping, were fundamental to the extensive use of barium titanate [11], [13].

1.3. Development of Lattice-Dynamic Aspects

ANDERSON [39] and COCHRAN [40] in 1960 attributed ferroelectric transformations to the instability of the crystal lattices with respect to certain lattice vibrations, so-called soft modes. Much earlier, FRÖHLICH [41] had associated the frequency ω_T of a transverse optical lattice vibration, which appears in the Lyddane – Sachs – Teller equation

$$\omega_T^2/\omega_L^2 = \varepsilon_\infty/\varepsilon_s$$

and anomalously high values of the static dielectric constant ε_s. However, the occurrence of a particularly soft TO mode and the consequent lattice instability if $\omega_T \to 0$ as $T \to T_c^+$ was clearly explained for the first time in 1960. In particular, COCHRAN attributed the vanishing of the force constants proportional to ω_T^2 at the transition temperature T_c of ionic crystals to an equilibrium between short-range repulsive forces and long-range attractive Coulomb forces.

The equations, which were presented in a form applicable only to certain cubic crystals, can be generalized to other lattices, and motivated a rapidly growing number of spectroscopic studies, utilizing infrared absorption, Raman scattering, and inelastic neutron scattering, which confirmed the theoretical predictions [10]. CHAVES and PORTO [42] used a frequency-dependent representation of the dielectric function $\varepsilon(\omega)$ to generalize the Lyddane – Sachs – Teller equation, including the case that the temperature-dependent low-frequency excitation responsible for the transformation has the character of a relaxation:

$$\frac{\varepsilon(\omega)}{\varepsilon_\infty} = \frac{i\omega_{\mathrm{LO}}+\omega}{i\omega_{\mathrm{TO}}+\omega} \prod_j \frac{\omega_{\mathrm{L}j}^2 + i\omega\gamma_{\mathrm{L}j} - \omega^2}{\omega_{\mathrm{T}j}^2 + i\omega\gamma_{\mathrm{T}j} - \omega^2} \tag{2}$$

Here ω_{TO} and ω_{LO} represent the transverse and longitudinal relaxation frequencies, respectively, and $\omega_{\mathrm{T}j}$ and $\omega_{\mathrm{L}j}$ the characteristic frequencies of the transverse and longitudinal oscillatory excitations, respectively. In ordered phases the structural changes can, to a first approximation, be identified as those atomic displacements that are described by the eigenvector of the soft mode. Conversely, the softening of a TO mode as a function of temperature became evidence for a ferroelectric transformation.

In proper ferroelectrics the soft mode has a wave vector $\boldsymbol{q} = 0$ (Γ point of the Brillouin zone), since the order parameter is homogeneous polarization. In improper ferroelectrics the corresponding wave vector $\boldsymbol{q}$ lies within, or on the boundary of, the first Brillouin zone. An example is gadolinium molybdate [*14985-14-9*], $Gd_2(MoO_4)_3$ [43]. The wave vector of the mode belonging to the order parameter lies at the boundary of the Brillouin zone; accordingly, below the transition temperature the unit cell is doubled. In this case the crystal symmetry permits a polarization proportional to the magnitude of the two-component order parameter, as well as a deformation. The resulting ferroelectric and ferroelastic properties of the ordered phase were correctly interpreted for the first time as effects of secondary order parameters by PYTTE [44].

Finally, the case that the instability involves a soft mode for which the wave vector $\boldsymbol{q}_{\mathrm{i}}$ lies in the interior of the first Brillouin zone is exemplified by potassium selenate [*7790-59-2*], K_2SeO_4. By means of inelastic neutron scattering, IIZUMI et al. [45] in 1977 found $\boldsymbol{q}_{\mathrm{i}} = (1-\delta(T))\,\boldsymbol{c}^*/3$, where $\boldsymbol{c}*$ is a reciprocal lattice vector. Below the transformation at T_{i}, the modulation imposed on the lattice, owing to the condition $\delta(T) \ll 1$, locally causes approximately a tripling of the unit cell. The temperature-dependent modulation is incommensurable with the lattice of the unordered phase and in the case of potassium selenate gives rise to a structure locally polar, but globally centrosymmetric and thus nonpolar. Potassium selenate becomes ferroelectric at a temperature $T_{\mathrm{c}} < T_{\mathrm{i}}$ as

$$\delta(T) \longrightarrow 0$$

and a commensurable phase that has a tripled unit cell is formed. The homogeneous polarization can be viewed as a secondary order parameter that drives this lock-in process.

For an understanding of ferroelectric transformations, structure determinations of the utmost precision have always been essential [2], [13]. Although considerable effort has been invested in X-ray and neutron diffraction studies, some qualitative and quantitative aspects still remain unelucidated, even for classical ferroelectrics such as barium titanate, because the shifts in atomic coordinates are frequently extremely small. If the symmetry of the disordered and ordered phases is known, a phenomenological description of a ferroelectric can often be accomplished within the experimental accuracy over a restricted temperature range by recourse to thermodynamic methods [7], but a general microscopic theory does not exist. The treatment of special models by the methods of the theory of phase transitions has been quite successful [8], [15].

2. Properties of Specific Families

Ferroelectric substances are customarily classified into families according to chemical and structural considerations [19], [20], although this approach distinguishes neither the type (order-disorder – displacive) nor the nature (ferroelectric – antiferroelectric, proper – improper) of the phase transformation. At present, the known pure compounds with ferroelectric properties number about two hundred, which are classified into about forty families [20]. In addition, there are numerous mixed systems, including many materials of commercial importance. In the following the properties of some

representative substances are presented. A short survey of characteristic data is given in Table 1.

Table 1. Curie points and spontaneous polarizations (at a specific absolute temperature) for various ferroelectric compounds

Substance	Curie point T_c, K	Spontaneous polarization P_s, μC/cm^2	
$PbTiO_3$	763	75	(295 K)
$LiNbO_3$	1483	71	(295 K)
$Ba_2NaNb_5O_{15}$	833	40	(295 K)
$Pb_5Ge_3O_{11}$	450	4.7	(295 K)
$Gd_2(MoO_4)_3$	432	0.29	(295 K)
SbSI	295	20	(273 K)
HCl	98.4	3.7	(95 K)
KH_2PO_4	123	4.7	(110 K)
$SC(NH_2)_2$	169	3	(140 K)
$Ca_2Sr(CH_3CH_2COO)_6$	283	0.9	(200 K)
$(NH_2CH_2COOH)_3 \cdot H_2SO_4$	323	4.5	(100 K)
$NaKC_4H_4O_6 \cdot 4H_2O$	297	0.24	(275 K)
K_2SeO_4	93	0.12	(40 K)

2.1. KH_2PO_4 (KDP) Family

The ferroelectric transition of potassium dihydrogen phosphate [*7778-77-0*] (KPD), KH_2PO_4, occurs at $T_c = 123$ K and is weakly first order. Potassium dihydrogen phosphate is tetragonal (point group $\bar{4}2\,m$) in the paraelectric phase and orthorhombic ($mm\,2$) in the ferroelectric phase, and thus is piezoelectric both above and below T_c. The static electromechanical properties of the material are represented by the coefficients of a series expansion of the energy density $U(D_j\,,\,\in_\mu)$ in the components of the dielectric displacement $\boldsymbol{D}$ and the elastic deformation $\in$. If the experimental boundary conditions require other independent variables, a suitable thermodynamic potential can be obtained by a Legendre transformation of U. In the case of KDP, such a Landau formulation yields the following fundamental linear piezoelectric equations

$$E_3 = \left(1/\varepsilon_{33}^{\in}\right) D_3 - h_{36} \in_6$$
$$\sigma_6 = -h_{36} D_3 + \left(1/s_{66}^{D}\right) \in_6$$

whereby the components in the polar c direction are taken into account. The only property of the material with an anomalous temperature dependence is the permittivity at constant deformation, $\varepsilon_{33}^{\in}$, which obeys a Curie – Weiss law (Eq. 1). For the usual experimental boundary conditions of constant field $\boldsymbol{E}$ and constant mechanical stress $\boldsymbol{\sigma}$,

$$1/\varepsilon_{33}^{\sigma} = 1/\varepsilon_{33}^{\in} - h_{36}^2 s_{66}^{D}$$
$$1/s_{66}^{E} = 1/s_{66}^{D} - h_{36}^2 \varepsilon_{33}^{\in} \qquad (3)$$

Then the "free" permittivity $\varepsilon_{33}^{\sigma}$ also obeys a Curie – Weiss law, but with a higher Curie temperature than the "clamped" permittivity $\varepsilon_{33}^{\in}$

$$T_{c,\sigma} = T_{c,\in} + h_{36} s_{66}^{D} \varepsilon_0 C$$

The elastic constant s_{66}^{E}, unlike s_{66}^{D}, is also temperature dependent. The effects described by Equations (3) are the result of symmetry-allowed coupling terms between the order parameter and other state variables in the expression for the energy density, and are characteristic of ferroelectrics [7].

Microscopic theories of the transformation of KDP begin with the structural units $H_2PO_4^-$ and K^+, which are pictured in Figure 1. The hydrogen bridges oriented at right angles to the tetragonal c axis connect adjacent phosphate tetrahedra, and for $T < T_c$ cooperatively order themselves in such a way that preferentially the two upper *or* the two lower protons lie near a phosphate tetrahedron. The resulting atomic displacements lead to spontaneous polarization. The pseudo-spin formalism often employed in connection with order – disorder transformations, together with the assumption of a tunnel mechanism of the protons along the hydrogen bridges, permits interpretation of many experimental observations, including a notable isotope effect: KD_2PO_4 [*13761-79-0*] has a transition temperature 90 K higher than that of KH_2PO_4 [10], [46].

Properties resembling those of KH_2PO_4 are found for RbH_2PO_4 [*13774-16-8*] ($T_c = 147$ K), KH_2AsO_4 [*7784-41-0*] (97 K), and RbH_2AsO_4 [*13463-57-8*] (110 K). The homologous ammonium compounds are antiferroelectric.

Preparation and Applications. KH_2PO_4 and its homologues can be prepared in the form of transparent single crystals from aqueous solutions at room temperature. Controlled growth is achieved by lowering the temperature or removing solvent from the saturated solutions in the presence of seed crystals. Occasionally a two-chamber process, with circulating solution, is employed. In one chamber polycrystalline

substance is taken up by a slightly unsaturated solution, in the other chamber single crystals grow at a somewhat lower temperature.

Members of the KDP family find use primarily by virtue of their good piezoelectric, electro-optical, and nonlinear optical properties. They are employed in the construction of Kerr cells, high-frequency light modulators, and optical frequency doublers.

2.2. Triglycine Sulfate (TGS) Family

Triglycine sulfate [*513-29-1*] (TGS), $(NH_2CH_2COOH)_3 \cdot H_2SO_4$, is ferroelectric at room temperature (point group 2) and at ca. 323 K is transformed into a centrosymmetric, paraelectric phase with the point group 2/*m*. The transition is second order; the static permittivity parallel to the ferroelectric direction obeys the Curie – Weiss law, at T_c exceeding $3\times10^5\,\varepsilon_0$. In the vicinity of T_c, the temperature dependence of the spontaneous polarization is given by $\boldsymbol{P}_s \propto (T_c - T)^{1/2}$,

in agreement with thermodynamic theory [7], [8]. Curves for $\boldsymbol{P}_s(T)$ and $\varepsilon_0/\varepsilon(T)$, which were determined by experiment, are shown in Figure 2.

Figure 2. Temperature dependence of the reciprocal relative permittivity $\varepsilon_0/\varepsilon$ and of the spontaneous polarization P_s of triglycine sulfate near T_c

TGS is considered an excellent example of a uniaxial ferroelectric of the order – disorder type. Essentially, the transformation is attributed to the dynamics of a nonplanar glycine group, which in the paraelectric phase possesses equivalent positions in a potential with a double minimum, thus giving rise to a crystallographic mirror plane of the average structure. The other two glycine groups of the unit formula are planar and are mirror images [47]. The nonequivalence of the glycine groups can be brought out by writing the compound as

$(NH_2CH_2COOH) \cdot (NH_3CH_2COOH)_2^+ SO_4^{2-}$

The spectrum of polarization fluctuations associated with the motions of the molecular dipoles can be measured in the form of the frequency dependence of the complex permittivity

$$\varepsilon(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega)$$

In the case of TGS, the dispersion of $\varepsilon(\omega)$ is well described [48] by the Debye form for a relaxation,

$$\varepsilon(\omega) = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/(1 + i\omega\tau) \tag{4}$$

The frequency $f_\varepsilon = 1/(2\pi\tau)$

likewise obeys a Curie – Weiss law and assumes the role of the soft transverse relaxation frequency in Equation (2). In the complex ε plane, the graphs for $\varepsilon(\omega)$ given by Equation (4) are semicircles. Figure 3 shows the curves for three temperatures.

Figure 3. Diagram of the relative complex permittivity $\varepsilon(\omega)/\varepsilon_0$ of triglycine sulfate at three temperatures [48]

Numerous other glycine compounds, such as triglycine selenate [*920-25-2*],

$(NH_2CH_2COOH)_3 \cdot H_2SeO_4$

and triglycine fluoroberyllate [*2396-72-7*],

$(NH_2CH_2COOH)_3 \cdot H_2BeF_4$

have properties similar to those of TGS. In each case the deuterated compounds are ferroelectric. The resulting increase in Curie temperature is small, 11 K in the case of TGS, so that the hydrogen bridges in these structures are considered to play no special role in the transformation.

Preparation and Applications. The water-soluble crystals are prepared by the same procedures as described for KDP (see page 6). If the linear growth rate is ca. 0.5 mm/day, growth of a 100-g single crystal takes ten weeks.

By virtue of its superb pyroelectric properties, TGS is used primarily in the construction of heat sensors, infrared detectors, and thermographic transducers. If the quantity $p/(c_p\varepsilon)$ is taken as the figure of merit of a pyroelectric detector, TGS has a favorable value at room temperature owing to its high pyroelectric coefficient $p = \partial P/\partial T$

and low permittivity ε [49].

Figure 4. Hysteresis loop of ferroelectric betaine arsenate (A) [50] and of antiferroelectric betaine deuteroarsenate (B) [51]

Betaine Compounds. Ferroelectric phases also exist for compounds of the amino acid betaine with various inorganic acids. Betaine arsenate, $(CH_3)_3NCH_2COO \cdot H_3AsO_4$, is ferroelectric below $T_c = 119$ K [50]. Betaine deuteroarsenate, $(CH_3)_3NCH_2COO \cdot D_3AsO_4$, has a transition temperature 53 K higher, which suggests a significant role of hydrogen bonds in the transformation. It is remarkable that, in contrast with betaine arsenate, betaine deuteroarsenate becomes antiferroelectric at 172 K [51]. The hysteresis loops in Figure 4 show the remanent polarization at $E = 0$, namely, P_r in the case of a ferroelectric, zero in the case of an antiferroelectric. Figure 4 also shows that sufficiently high fields convert the antiferroelectric state into a ferroelectric one. The height of the subloops indicates the twofold polarization of a sublattice.

2.3. $(NH_4)_2SO_4$ (AS) Family

The ferroelectrics included in the $(NH_4)_2SO_4$ (AS) family belong to the extensive group of substances with the empirical formula A_2BX_4 that in their paraelectric high-temperature phase have the β-K_2SO_4 structure and exhibit ferroelectric properties in various low-temperature phases. Examples are $(NH_4)_2SO_4$ [*7783-20-2*], K_2SeO_4, Rb_2ZnCl_4 [*33724-11-7*], and some homologous compounds. For these compounds the polarization is, as a rule, not the primary order parameter, and in many cases a transition into an incommensurably modulated structure occurs above the ferroelectric transition (see Section 1.3).

A special case is that of $(NH_4)_2SO_4$, which at 223 K undergoes a transition from the paraelectric to a spontaneously polarized low-temperature phase. The transition is first order. The temperature dependence of the spontaneous polarization is shown in Figure 5: P_s reaches zero near 85 K, and its sign changes on further cooling [52]. In this case, distinct sublattices with opposite but no equal polarization give rise to ferrielectric behavior resembling ferrimagnetism.

Figure 5. Temperature dependence of the spontaneous polarization of ferrielectric ammonium sulfate [52]

2.4. Oxidic Ferroelectrics

The most numerous, and commercially the most important, group of ferroelectric substances are oxides. Among these, the perovskites have been most intensively studied; they also find the most extensive industrial application in the form of polycrystalline ceramics.

2.4.1. Barium Titanate

Of all ferroelectrics, the one most thoroughly studied is barium titanate [*12047-27-7*], $BaTiO_3$. The paraelectric perovskite structure (Fig. 6) is cubic and dielectrically isotropic. Below the 403 K Curie point, essentially as the result of a relative displacement of the oxygen and titanium sublattices, there arises a dipole moment parallel to one of the cubic axes and a tetragonal distortion of the unit cell. On further reduction of the temperature, corresponding displacements and dipole moments also arise parallel to the cubic axes of the original phase that were initially not affected. As a consequence, at 278 K the crystal assumes an orthorhombic, and finally at 183 K, a rhombohedral structure. For the orthorhombic structure, $\boldsymbol{P}_s$ is parallel to a face diagonal of the original cubic cell. For the rhombohedral case $\boldsymbol{P}_s$ is parallel to a body diagonal of the original cubic cell. The permittivity obeys the Curie – Weiss law in the paraelectric phase and below the first transition experiences an especially sharp drop parallel to the polar direction (here the *c* axis, Fig. 7). An analogous temperature effect is observed for the lower-temperature transitions. In its simplest form, the thermodynamic description by Devonshire [29] of the ferroelectric transformations of $BaTiO_3$ begins with an expansion of the free elastic enthalpy density *G* in powers of the components of the polarization $\boldsymbol{P}$, while the external mechanical stress is taken to be zero:

$$\begin{aligned} G = G_0 &+ \frac{1}{2}\alpha\left(P_a^2+P_b^2+P_c^2\right) \\ &+ \frac{1}{4}\beta\left(P_a^4+P_b^4+P_c^4\right) \\ &+ \frac{1}{2}\gamma\left(P_a^2P_b^2+P_b^2P_c^2+P_c^2P_a^2\right) \\ &+ \frac{1}{6}\delta\left(P_a^6+P_b^6+P_c^6\right) \end{aligned} \tag{5}$$

where G_0 is the enthalpy density of the cubic reference phase. The individual terms in the expansion are found as the expressions invariant with respect to the symmetries of the reference phase. The equilibrium conditions

$$\partial G/\partial P_i = E_i = 0$$

lead to the desired solutions:

$P_a = P_b = P_c = 0$	for the paraelectric, cubic phase
$P_a = P_b = 0 \quad P_c \neq 0$	for the tetragonal phase
$P_a = 0, P_b = P_c \neq 0$	for the orthorhombic phase
$P_a = P_b = P_c \neq 0$	for the rhombohedral phase

Figure 6. Unit cell of cubic barium titanate. The arrows indicate the atomic displacements that result in the tetragonal structure of the ferroelectric phase.

The temperature is explicitly introduced into the function *G* by the assumption that

$$\alpha = \alpha_0\,(T - T_0)$$

This form of the coefficient α can be justified on phenomenological [54] and latticedynamic grounds [40]. Through the relation $1/\chi = \partial^2 G/\partial P^2$,

it leads to the Curie – Weiss law. The coefficients β, γ, and δ of the expansion are, to a first approximation, viewed as temperature independent. For the spontaneous polarization of the tetragonal phase subject to equilibrium constraints, Equation (5) gives the result:

$$P_c^2 = -\,(\beta/2\delta) \pm \left[\beta^2/\left(4\delta^2\right) - \alpha_0\,(T - T_0)\right]^{1/2}$$

In the case of barium titanate, $\beta < 0$, and the transition is first order [5], [29]. The maximum thermal hysteresis for the transition at 403 K is 10 K.

Figure 7. Lattice distortions and temperature dependence of the relative permittivitiy of $BaTiO_3$
The numerical values in all phases are for the orientations parallel (ε_c) and perpendicular (ε_a) to the tetragonal axis. In the two low-temperature phases they are only crude estimates, since in those cases the crystal has different principal axes of the dielectric tensor, and in general there is no single domain state [53].

Barium titanate was long viewed as an example of a displacive-type ferroelectric. However, structural investigations have shown that the thermal displacements of the atoms exhibit considerable anharmonicity, so order – disorder mechanisms also had to be taken into consideration. Results of infrared measurements [55] and hyper-Raman scattering [56] for the soft mode can be described within experimental error by either an oscillator model or a relaxator model. Oscillator parameters for the soft mode obtained by hyper-Raman scattering are plotted in Figure 8.

Preparation and Applications. Single crystals of $BaTiO_3$ can be obtained in sizes up to $10\,cm^3$ by lowering the temperature of a variety of fluxes, which include KF, $BaCl_2$, or excess TiO_2. Especially good results are obtained with the top-seeded solution growth technique and a TiO_2-rich melt at ca. 1630 K [16].

The standard technique of pulling single crystals out of the pure melt cannot be used for cubic barium titanate, for the melt (*mp* 1891 K) produces a hexagonal phase, which at 1733 K

Figure 8. Temperature dependence of frequency ω_T (●) and damping coefficient γ_T (▲) of the soft mode of barium titanate obtained from measurements of the hyper-Raman effect [56]

converts into the cubic form, with consequent destruction of the crystals.

The technical uses of barium titanate single crystals are limited. As a material with a strong linear electro-optic effect, it is above all a candidate for use in light modulators, as well as for applications in dynamic holography, optical image intensification, and phase conjugation optics [57].

2.4.2. Other Oxides of the Perovskite Type

Other examples of oxidic perovskites include the ferroelectrics $KNbO_3$ [*12030-85-2*] and $PbTiO_3$ [*12060-00-3*], which wholly or partly duplicate the succession of phases exhibited by $BaTiO_3$, as well as the antiferroelectrics $PbZrO_3$ [*12060-01-4*] and $NaNbO_3$ [*12034-09-2*]. Other perovskites, for example $KTaO_3$ [*57126-93-9*], show a dielectric behavior conforming to the Curie – Weiss law, but no ferroelectric transition is observed down to low temperatures (incipient ferroelectrics). At temperatures below ca. 2 K quantum-mechanical zero-point vibrations can suppress the expected ferroelectric ordering. The ranks of ferroelectric perovskites are extended by a multitude of complex compounds as well as solid solutions of simple or complex perovskites [19], [20].

2.4.3. $LiNbO_3$ Family

The trigonal lattice structure of $LiNbO_3$ [*12031-63-9*] contains oxygen octahedra that are connected through their faces and that contain Li, Nb, or no atom at all at their center. (The oxygen octahedra in perovskite, in contrast, are connected through their corners.) The ferroelectric transition occurs at $T_c = 1483$ K, thus only slightly below the melting point of 1526 K. A member of the same family, $LiTaO_3$ [*12031-66-2*], has a substantially lower Curie point, $T_c = 893$ K.

Preparation and Applications. Lithium niobate and lithium tantalate can be produced as single crystals of centimeter dimensions and good optical quality from their melts by the Czochralski technique. The acentricity at room temperature associated with the high spontaneous polarization gives rise to strong piezoelectric, electro-optic, and nonlinear optical effects. Because of these properties, the materials find use in electro-acoustic filters, light modulators, optical amplifiers, and frequency multipliers [13], [57].

Materials with high electro-optical coefficients and high photoconductivity exhibit light-induced changes in refractive index. This *photorefractive effect* is a consequence of the presence of fields associated with space charges that are formed under conditions of nonhomogeneous illumination. The mechanism is that charge carriers freed by light from defects are captured by traps in locations where the light intensity is low. Good photorefractive properties, of use in the storage of phase holograms and for optical image processing, are found in $LiNbO_3$ and $KNbO_3$, but also in $BaTiO_3$ and in $Ba_2NaNb_5O_{15}$ [*12323-03-4*], a compound of the tungsten bronze type. Photoconductivity is often achieved by suitable doping, e.g., with iron.

2.5. Ferroelectric Ceramics

Perovskite-based ceramics are commercially produced in large quantities and find use principally in capacitors and positive temperature coefficient (PTC) thermistors and as piezoceramics.

Barium titanate ceramic is employed as a dielectric in capacitors. The dependence of the permittivity on temperature and field strength, which as a rule is undesirable, can be minimized by partial substitution of Sr or Pb for Ba as well as Zr or Sn for Ti. At the same time, the transition, which in any case is diffuse in heavily doped barium titanate, can be lowered to room temperature, thus achieving high permittivities [11]. Attention must also be paid to the grain size, because of the associated depolarization effects.

Light doping, e.g., a few tenths of mole percent of Sb, Nb, or rare earth, makes barium titanate semiconducting. If the ceramic also contains traces of Cu, Fe, or Mn, accumulation of these elements at the grain boundaries causes electrically insulating layers to form, since these impurities, as acceptors, capture free electrons.

If the acceptor concentration is sufficiently high, the ceramic constitutes a blocking layer capacitor with high effective permittivity. Lighter doping (< 0.01 %) produces so-called PTC thermistors; their resistivity can increase by more than four orders of magnitude in a 100-K interval above the Curie temperature (Fig. 9) [58]. Below the Curie point the potential barriers at the grain boundaries are nullified by polarization charges of the ferroelectric crystallites, and the electric resistance of the ceramic is determined by that of the semiconducting grains.

Figure 9. Temperature dependence of the resistivity of barium titanate ceramic PTC thermistors with various Curie temperatures

For piezoelectric applications the macroscopically isotropic ferroelectric ceramic is polarized in electric fields. The optimal orientation of the spontaneous polarization in the randomly arranged grains is facilitated by elevated temperatures. Ceramics of lead titanate – lead zirconate solid solutions (PZT) [*12626-81-2*] are particularly well suited for piezoceramic applications by virtue of their high Curie temperatures and high spontaneous polarization as well as their crystallographic properties. The phase diagram is shown in Figure 10. Materials with a composition close to that of the morphotropic phase boundary between the zirconate-rich rhombohedral phase and the titanate-rich tetragonal crystal structure exhibit coupling factors up to $k = 0.7$, where k^2 is the fraction of the electric energy supplied that is stored as mechanical energy [6], [11].

Figure 10. Phase diagram of the $PbTiO_3 - PbZrO_3$ (PZT) solid solution
AF = antiferroelectric; F = ferroelectric; P = paraelectric

The good electro-optical properties of oxidic ferroelectrics and the advantages of ceramic materials are incorporated in *opto-ceramics*. High transparency is achieved by selection of phases of minimal optical anisotropy and by special sintering procedures as in the case of lanthanum-doped lead titanate – lead zirconate (PLZT) [13, pp. 540 – 544]. Materials with the composition $Pb_{1-1.5x}La_x \square_{0.5x}(Zr_{0.65}Ti_{0.35})O_3$ with $0.07 < x < 0.1$ are used for electro-optical components such as readouts or optical shutters.

Preparation. Ferroelectric ceramics are prepared by sintering the oxide mix for several hours at temperatures between ca. 1450 and 1650 K. Starting materials are the milled oxides or, for especially fine-grained products, compounds prepared by wet-chemical methods. The low-porosity ceramics required for optical appli-

cations are obtained by hot pressing or vacuum sintering [11].

2.6. Ferroelectric Polymers and Liquid Crystals

Mechanically stretched and electrically polarized foils of the semicrystalline polymer poly-(vinylidene fluoride) [*24937-79-9*] (PVDF),

exhibit strong piezoelectric and pyroelectric effects. The further observation that PVDF shows dielectric hysteresis led to the assumption that it is ferroelectric, although no phase transition occurs up to the melting point (~ 440 K) of the crystallites of the orthorhombic β phase. Models proposed by KEPLER [59] and by BROADHURST et al. [60] assume cooperative motions of the polar chain molecules and predict a maximum spontaneous polarization of 22 μC/cm^2. A study of copolymers of PVDF with polytrifluoroethylene [61] found evidence for a transformation of a nonpolar high-temperature phase into a ferroelectric low-temperature phase.

Ferroelectric polymers find applications principally as piezoelectric transducers in the form of thin foils.

Ferroelectric properties of liquid crystal systems were first predicted in 1975 by MEYER and collaborators [62], [63]. The required symmetry constraints are satisfied by certain mesogenic phases found in the smectic group of liquid crystals: in the so-called C$*$ phase, rod-shaped, chiral molecules are arranged in layers. The long axes of the molecules are parallel to each other and inclined at an equal angle to the plane of the layer; thus, the macroscopic symmetry belongs to the monoclinic class 2. The polar axis lies parallel to the twofold rotational axis in the plane of the layer. However, the chiral character of the molecules causes the molecular axes in adjacent layers to assume a helical arrangement with respect to the normal to the layer. Consequently, a macroscopic polarization does not arise in the field-free state. In a sufficiently strong electric field directed parallel to the planes of the layers, the direction of the spontaneous polarization can be altered as in the case of a regular ferroelectric. An example of such a liquid crystal ferroelectric is *p*-decyloxybenzylidene-*p*′-amino-2-methyl-butyl-cinnamate [*97335-57-4*]:

The phase transformations of this system have been studied in detail [64], [65]. As for incommensurable systems, the dielectric polarization is not the primary order parameter for this system.

11.3.2. Development of Fertilizer Consumption

Fertilizers are products that improve the levels of available plant nutrients and/or the chemical and physical properties of soil. An overview is given over the chemical and physical aspects of plant nutrition uptake and soil properties. The different categories of fertilizers are discussed, and special interest is given on production processes and analyses, including storage and transportation as well as environmental, legal, and economic aspects.

[Top of Page]

1. Introduction

Heinrich W. Scherer and Konrad Mengel

Fertilizers in the broadest sense are products that improve the levels of available plant nutrients and/or the chemical and physical properties of soil, thereby directly or indirectly enhancing plant growth, yield, and quality.

Fertilizers are classified as follows in terms of their chemical composition:

1. Mineral fertilizers consist of inorganic or synthetically produced organic compounds.
2. Organic fertilizers are waste products from animal husbandry (stable manure, slurry manure), plant decomposition products (compost, peat), or products from waste treatment (composted garbage, sewage sludge).
3. Synthetic soil conditioners are products whose main function is to improve the physical properties of soils, for example, friability and water and air transport.

The following categories are distinguished with respect to nutrient content:

1. Straight fertilizers generally contain only one primary nutrient.
2. Compound (complex or multinutrient) fertilizers contain several primary nutrients and sometimes micronutrients as well.
3. Micronutrient fertilizers contain nutrients required in small quantities by plants, as opposed to macronutrients; quantities range from 1 to 500 g $ha^{-1}a^{-1}$.

Finally, fertilizers can be classified as solid or liquid fertilizers and as soil or foliar fertilizers, the latter being applied exclusively by spraying on an existing plant population.

History. Fertilizing substances were applied even in antiquity. Their use can be attributed to the observation in nature that plants developed especially well in locations where human or animal excreta, ash residues, river mud, or dying plants were left. For example, the Egyptians knew about the fertility of the Nile mud, and the Babylonians recognized the value of stable manure; for example, HOMER mentions manure in the *Odyssey*. PLINY reports that the Ubians north of Mainz used “white earth,” a calcareous marl, to fertilize their fields. The Romans acknowledged the advantages of green manuring, cultivating legumes and plowing them under. At the end of the first millenium, wood ash was much used as fertilizer in Central Europe. Not until the beginning of the 19th century did guano, at the suggestion of ALEXANDER VON HUMBOLDT (1800), and Chilean caliche, on the recommendation of HAENKES (1810), come into use as fertilizers. Up to that time, however, it was still believed that the organic matter of soil, humus, was the true source of plant nutrition.

Around 1800, the nutrition problem entered a critical phase in Europe. In 1798, MALTHUS set forth his pessimistic theses, saying that the quantity of food could increase only in arithmetic progression while the population grew geometrically. Combining results obtained by others (SPRENGEL, BOUSSINGAULT) with his own pathbreaking studies, J. VON LIEBIG set forth the theoretical principles of plant nutrition and plant production in *Chemistry in Its Application to Agriculture and Physiology* (1840). He took the view, now considered obvious, that plants require nitrogen, phosphate, and potassium salts as essential nutrients and extract them from the soil. LIEBIG's *mineral theory* was well supported by experimental data of J. B. BOUSSINGAULT (1802 – 1887) in France. He and also J. B. LAWES (1814 – 1900) and J. H. GILBERT (1827 – 1901) in England showed that plants benefit from inorganic N fertilizers. LIEBIG thus became the founder of the theory of mineral fertilizers, and his doctrines led to an increasing demand for them. A number of companies were subsequently founded in Europe to produce phosphate and potash fertilizers. Superphosphate was manufactured for the first time in 1846, in England.

In Germany, this industrial development started in 1855. The importation of saltpeter on a large scale began in the area of the German Federation (56 000 t in 1878). Peruvian guano soon came into heavy use (520 000 t in 1870). Ammonium sulfate, a coke-oven byproduct, was later recognized as a valuable fertilizer, and the mining of water-soluble potassium minerals was undertaken in the 1860s [1].

The demand for nitrogen that developed at the end of the 19th century soon outstripped the availability of natural fertilizers. A crucial breakthrough came about with the discovery and large-scale implementation of ammonia synthesis by HABER (1909) and its industrial realization by BOSCH (1913).

Around the turn of the century, the technique of hydroponics led to the discovery of other essential plant nutrients. Research showed that plants in general require ten primary nutrients: carbon, hydrogen, oxygen. nitrogen, phosphorus, potassium, calcium, magnesium, sulfur, and iron. JAVILLIER and MAZE (1908) pointed out for zinc and AGULHON (1910) pointed out for boron the nutritional effects on plants. WARINGTON (1923) first described the symptoms of boron deficiency, and BRANDENBURG (1931) clearly recognized dry rot in the sugar beet as boron deficiency. Generally micronutrients were made available to the plant as liquid foliar fertilizer, a method first suggested for iron by GRIS in 1844. By 1950, this list of micronutrients had been expanded to include manganese, copper, and molybdenum.

Almost 70 years ago, serious research began on the best nutrient forms for individual plant species under various soil and climatic conditions. Besides the classical fertilizers, for example, controlled-release fertilizers, improved foliar fertilizers, nutrient chelates, and nitrification inhibitors have been developed in

recent decades. This development of new nutrient forms is still in full swing in the special fertilizers sector.

In the developed market economies of Western Europe, the United States, and Japan, however, the level of mineral fertilizer use has not been increasing since the beginning of the 1980s. In some countries, genuine agricultural overproduction has occurred recently. Since better delivery of plant nutrients has led to increasing self-reliance even in the Third World economies (e.g., China, India, Brazil), these countries are not so important as purchasers of nutrients on the world market, so that surpluses cannot be exported without limit. The production of fertilizers is also on the increase in these countries. Thus overproduction plus regional environmental problems (nitrates entering the ground water) are actually leading to a decrease in mineral fertilizer use in some areas. This decline will be limited by diminishing soil fertility in localities where fertility has been enhanced by decades of proper fertilization.

2. Plant Nutrition and Soil Science

Heinrich W. Scherer and Konrad Mengel

The science of plant nutrition is situated between soil science and plant physiology. It comprises the definition of the elements nutritive for plants; the uptake of plant nutrients and their distribution in the plant; the function of the nutritive elements in plant metabolism; their effect on plant growth; yield formation and quality parameters in crops; soil nutrient exploitation by plant roots; factors and processes that control the plant nutrient availability in soils; toxic elements in soils and their impact on plant growth; the application of plant nutrient carriers (fertilizers) and their turnover in soils; nutrient balance; and the maintenance of soil fertility.

Plant nutrition is considered mainly from two aspects, an agronomic one and an ecological one. The former is focused on the question of fertilizing soil as an efficient means to increase crop yield and to maintain or even improve soil fertility. The latter, the ecological aspect of plant nutrition, is concerned with the nutritive condition of a soil and a location and with its effect on plant growth and plant communities. Since fertilizers are the topic of this article, the agronomic aspects of plant nutrition are treated with greater depth.

The science of plant nutrition is closely associated with the science of soils. The latter comprises a broad field of scientific activity and thus cannot be considered here in all its facets. In this article only those problems of soil science relevant to understanding plant nutrition are treated.

2.1. Plant Nutrients

2.1.1. *Definition and Classification*

From a scientific point of view, the term plant nutrient is not especially precise. More appropriate is to distinguish between nutritive elements of plants and nutritive carriers. Essential *nutritive elements* for plants are the chemical elements that are required for a normal life cycle and that satisfy the following criteria:

1. A deficiency of the element makes it impossible for the plant to complete its life cycle.
2. The deficiency is specific for the element in question.
3. The element is directly involved in the nutrition of plants because of either its chemical or its physical properties.

According to this definition, the following chemical elements are nutritive elements for plants: C, H, O, N, P, S, K, Ca, Mg, Fe, Mn, Cu, Zn, Mo, B. Further elements, such as Na, Cl, and Si, may affect plant growth positively, and there are particular plant species for which these elements are of great importance. Nevertheless, they are not essential nutritive elements for plants in the strict sense of the definition. Cobalt is required by some bacteria, e.g., by dinitrogen-fixing bacteria and thus may also benefit plant growth indirectly.

Generally it is not the element itself that is provided to and taken up by the plant, but an ion or a molecule in which the nutritive element is present, e.g., C is present in CO_2, P in $H_2PO_4^-$, N in NO_3^- or NH_4^+, and B in H_3BO_3. The particular molecule or ion in which the nutritive element is present is termed the *nutrient carrier*. In the case of metals, the corresponding ion or salts of ion species in question, e.g., K^+, Ca^{2+}, Zn^{2+}, can be considered the carrier. In this sense fertilizers are nutrient carriers.

Plant nutrients may be grouped into macronutrients and micronutrients. *Macronutrients* are required in high amounts and thus are present in plant tissues in much higher concentrations than the *micronutrients*. Carbon, H, O, N, P, S, K, Ca, and Mg belong to the macronutrients. Their concentration in the dry plant matter is in the range 1 – 50 mg/g, except for C, H, and O, which have much higher concentrations (see Table 2). The concentration of the micronutrients in the dry plant matter is in the range 1 – 1000 µg/g.

From the viewpoint of fertilization, those nutrients that are required by plants in high quantities and that must be regularly supplied by fertilization are of particular interest. These nutrients are N, K, P, and to a minor degree also Ca, Mg, and S. Calcium is a *soil nutrient*, which means that it is important for an optimum soil structure. Application of micronutrients is not a common practice, but they are applied at locations where soils are low in a particular micronutrient or where soils may bind this micronutrient very strongly. This is the case for heavy metals (Fe, Mn, Cu, Zn) and B in calcareous and alkaline soils (soils with a high pH value), while Mo is strongly fixed in acid soils. Acid organic soils are known for their low available Cu content.

According to the different quantitative requirements for macronutrients and micronutrients, the former are taken up in much higher quantities than the latter. Thus a wheat stand with a yield potential of 7 t of grain per hectare requires about 100 kg K but only 100 g Cu.

From a physiological point of view, plant nutrients are grouped into four groups, as shown in Table 1. The *first group*, comprising C, H, O, N, and S, includes all major elementary constituents of organic plant matter. Their carriers are present mainly in the oxidized form, and they must be reduced during the process of incorporation. The energy required for this reduction originates directly or indirectly from photosynthetically trapped energy. Assimilation of H is basically an oxidation process, namely, the oxidation of water with the help of light energy (photolysis):

Table 1. Physiological classification of plant nutritive elements, nutrient carriers, and form in which the nutrient is taken up

Nutritive element	Nutrient carrier	Uptake
First group		
C	CO_2, HCO_3^-	CO_2 by leaves, HCO_3^- by roots
H	H_2O	H_2O by leaves, H_2O and HCO_3^- by roots
O	CO_2, HCO_3^-, O_2	O_2 and CO_2 by leaves, HCO_3^- and O_2 by roots
N	NH_4^+, NH_3, NO_3^-, NO_x	NH_4^+ and NO_3^- by roots, NH_3 and NO_x by leaves
S	SO_4^{2-}, SO_2, SO_3, H_2S	SO_4^{2-} by roots, SO_2, SO_3, and H_2S by leaves
Second group		
P	$H_2PO_4^-$, HPO_4^{2-}	$H_2PO_4^-$ and HPO_4^{2-} by roots
B	H_3BO_3, borates	H_3BO_3 and $B(OH)_4^-$ by roots
Si	silicates	$Si(OH)_4$ by roots
Third group		
K	K^+, K salts	K^+ by roots
Mg	Mg^{2+}, Mg salts	Mg^{2+} by roots

Ca	Ca^{2+}, Ca salts	Ca^{2+} by roots
Mn	Mn^{2+}, Mn salts	Mn^{2+} by roots
Fourth group		
Fe, Cu, Zn, Mo	ionic form or metal chelates, minerals containing these elements	by roots in ionic form or in the form of soluble metal chelates, Mo in the form of the molybdate

$$H_2O \xrightarrow{h\nu} 2H^+ + 2e^- + 0.5\,O_2$$

The *second group* (P, B, Si) comprises elements that are taken up as oxo complexes in the partially deprotonated (P) and protonated (B, Si) form. The oxo complex is not reduced in the plant cell, but may form esters with hydroxyl groups of carbohydrates, thus producing phosphate, borate, and silicate esters.

The *third group* comprises metals that are taken up from the soil solution in ionic form. They are only partially incorporated into the organic structure of the plant tissue: Mg in the chlorophyll molecule, Mn in the electron donor complex of photosystem II, and Ca^{2+} as countercation of indiffusible anions in cell walls and particularly in biological membranes. Potassium is virtually not incorporated into the organic plant matter. It is only weakly adsorbed by Coulombic forces. There exist, however, some organic molecules that may bind K^+ very selectively (ionophores, see Section Nutrient Uptake and Long-Distance Transport in Plants). These ionophores are likely to be involved in K^+ uptake.

The *fourth group* comprises heavy metals, of which Fe, Cu, and Zn are taken up as ions or in the form of soluble metal chelates, while Mo is taken up as molybdate. These molecules are easily incorporated into the organic structure, where they serve as essential elements of enzyme systems: Fe in the heme group and in ferredoxin, Mn in arginase [2], Cu in oxidases (polyphenol oxidase, cytochrome oxidase, ascorbate oxidase [3]), Zn in RNA polymerase [4], and Mo in nitrate reductase [5] and nitrogenase [6].

All nutritive elements of plants, therefore, are taken up in the form of inorganic complexes, mostly in oxidized form or as metal ions, i.e., in forms characterized by a low energy level. This is a unique feature of plants, and a feature in which they contrast sharply with animals and most kinds of microorganisms (bacteria and fungi). Animals and most microorganisms must take up food that is rich in chemical energy in order to meet their energy requirements. Plants, at least green plants, meet their energy requirement by converting radiation energy into chemical energy. This energy conversion process is manifest in the reduction of plant nutrient carriers (NO_3^-, SO_4^{2-}, CO_2) as already mentioned. Thus important processes of plant nutrition are closely linked with the unique function of plants in the great cycle of nature, i.e., the conversion of inorganic matter into organic form. Liebig [7] was correct in commenting on plant nutrition: “Die ersten Quellen der Nahrung liefert ausschließlich die anorganische Natur.” (The primary source of nutrition is provided exclusively by the inorganic materials in nature.)

2.1.2. *Function of Plant Nutrients*

Most plant organs and particularly plant parts that are metabolically very active, such as young leaves and roots, are rich in water (ca. 80 – 90 wt % of the total fresh matter), while their organic material is ca. 12 – 18 wt % and their mineral content is 2 – 6 wt %. As shown in Table 2, in the dry matter of plant material O and C are by far the most abundant elements, followed by H, N, and K. The elements C, O, H, and, to some extent, N are mainly structural elements in plant matter. They can, however, form chemical groups that are directly involved in metabolic processes, e.g., carboxyl groups, amino groups, hydroxyl groups.

Table 2. Mean content of chemical elements in the dry matter of green plant material

Element	Content, g/kg
O	440
C	420
H	60
N	30
K	20
P	4
All other elements	26

Since in many soils the available N is low, *nitrogen* [7727-37-9] is the most important fertilizer element, and for this reason its function in plant metabolism deserves particular interest. Nitrogen is an essential element for amino acids, proteins, nucleic acids, many coenzymes, and some phytohormones. Basic biochemical processes of meristematic growth, such as the synthesis of proteins and nucleic acids, require N. If this nutrient is not supplied in sufficient amounts, the growth rate is depressed and the synthesis of proteins affected. Nitrogen-deficient plants are characterized by low protein and high carbohydrate contents. This relationship is shown in Table 3 [8].

Table 3. Effects of N supply on yield of dry matter and the content of organic N and carbohydrates in the dry matter of young timothy plants (*Phleum pratense*) [8]

Yield and content	N supply	
	Low	Sufficient
Yield, g/pot	15.7	20.2
Content, mg/g		
Organic N,	20.5	31.5
Sucrose	46.9	22.6
Fructans *	22.2	9.2
Starch	32.8	11.7
Cellulose	169	184

* Polysaccharides of fructose.

Nitrogen is also essential for the formation of chloroplasts, especially for the synthesis of chloroplast proteins. Hence N deficiency is characterized by low chlorophyll content; the leaves, especially the older ones, are pale and yellow; the stems thin and the plants small. Nitrogen-deficient plants senescence earlier, probably because of a deficiency of the phytohormone cytokinin. Abundant N supply increases the protein content, especially the content of free amino

acids, and often also the content of NO_3^- in plants. An example of this is shown in Table 4 [9]. Excess nitrogen nutrition results in luxurious plants that frequently are susceptible to fungi attack.

Table 4. Relationship between N fertilizer rate and nitrogenous fractions in the dry matter of rye grass [9]

Nitrogen fertilizer rate, kg/ha	Nitrogenous fraction, g/kg			
	Total N	Protein N	Free amino acid N	NO_3^- and NO_2^- N
0	13.2	9.8	1.6	0.4
110	18.9	12.6	2.1	0.6
440	37.3	20.6	5.6	3.5

The ratio of N to S in plant matter is ca. 10 : 1. Hence *sulfur* [7704-34-9] is required in much lower quantities than N. Their functions are, however, similar. Sulfur is an elementary constituent of most proteins; the SH group in involved in various enzymatic processes and it is the reactive group of coenzyme A. Disulfide (S – S) bridges are essential structural elements in the tertiary structure of polypeptides and in many volatile S compounds, such as diallyl disulfide, which is the main component in garlic oil. Mustard oils occurring in many species of the Cruciferae contain a S-glycosidic bond and a sulfuryl group:

Insufficient S supply results in a decrease of growth rate with extremely low levels of SO_4^{2-} and high concentrations of free amino compounds and NO_3^- in the leaves, which is due to hampered protein synthesis. Sulfur plays an important role in the baking quality of wheat, since the concentration of S compounds in the gluten fraction is responsible for the linkages between the protein molecules [10]. Sulfur deficiency may also affect N_2 fixation of legumes by causing unfavorable conditions in the host plant or because of the relatively high S content of nitrogenase and ferredoxin [11]. Deficiency symptoms of S appear at first in the youngest leaves, which turn light green to yellow. Abundant supply with S results in an accumulation of sulfate in plant tissues.

Sulfur oxide can be taken up by the leaves and metabolized and thus can contribute to the S nutrition of plants. Too high SO_2 concentrations in the atmosphere may be toxic. The toxicity symptoms are necrotic spots in the leaves. According to SAALBACH [12], the critical SO_2 level in the atmosphere for annual plants is 120 µg/m^3. For trees and other perennials it is about half this level. The currently much discussed damage to trees in the forest of the Federal Republic of Germany (mainly spruce and silver fir) is not caused by toxic SO_2 levels.

Phosphorus [7723-14-0] is an essential element in nucleic acids and various phospholipids (phosphoglyceride and phosphosphingolipids). In both cases. phosphate is esterified with sugars (nucleic acid) or with alcohol groups of glycerol or sphingosine. Phosphate is also present in various coenzymes; the most prominent is adenosine triphosphate (ATP), which carries a kind of universal energy that is used in a number of biochemical processes. Metabolites and enzymes can be activated by phosphorylation, a transfer of the phosphoryl group from ATP to the metabolite according to the following reactions:

Activation of glucose

Glucose + ATP ⇒ Glucose-6-phosphate + ADP

Phosphorylation of an enzyme

Enzyme – OH + ATP ⇒ Enzyme–O(P) + ADP

Such reactions demonstrate the essential role of P not only in plant metabolism but also in all living organisms. Undersupply with P results in a reduced growth rate, and seed and fruit formation is affected. The leaves of P-deficient plants often show a gray dark green color; the stems may turn red. The P reserve in seeds is the Mg (Ca) salt of the inositol hexaphosphate (phytic acid):

Myo–inositol hexaphosphate

Phosphoryl group

The physiological role of boron has remained obscure until now, and therefore various hypotheses with numerous modifications exist concerning the physiological and biochemical role of boron in higher plants. Depending on the pH of the soil, boron seems to be taken up mainly as undissociated boric acid or as the borate anion. Plant species differ in their boron uptake capacity, reflecting differences in boron requirements for growth. However, there is still some controversy about boron translocation in plants. At least in higher plants, a substantial proportion of the total boron content is complexed in the cell walls in in a *cis*-diol configuration [14]. According to BIRNBAUM et al. [13], B is involved in the synthesis of uracil and thus affects UTP formation. (UTP is an essential coenzyme for the synthesis of sucrose and cell-wall components.) Also the synthesis of ribonucleic acid is hampered in the case of B deficiency. Since uracil is an integral part of ribonucleic acid (RNA), the formation of RNA may also be related to the synthesis of uracil. POLLARD et al. [15] suggest that B has a specific influence on plant membranes by the reaction of borate with polyhydroxy compounds.

Boron deficiency appears as abnormal or retarded growth of the apical growing points. The youngest leaves are misshapen and wrinkled and show a darkish blue-green color. The fact that B deficiency primarily affects the apex is in accord with the impaired synthesis of ribonucleic acids required for meristematic growth. High levels of available B in the soil may cause B toxicity in plants. This is mainly the case in arid areas; however, B toxicity can also be the consequence of industrial pollution [16]. The toxicity is characterized by yellow leaf tips followed by progressive necrosis. The leaves take on a scorched appearance and drop prematurely.

Silicon [7440-21-3] is not an essential element for plants; however, it has a beneficial effect on various plant species, mainly grasses [17]. In plants well supplied with Si, cuticular water losses are diminshed and resistance against fungal attack is improved [18]. The favorable effect of Si on rice growth is well known. Silicon-containing fertilizer is frequently applied in rice production.

Among the metal cation species, *the potassium* [7440-09-7] *ion*, K^+, is the nutrient plants take up from the nutrient medium at the highest rates. The K^+ concentration in the cytoplasm is about 100 mM and thus much higher than the concentration of other ion species [19]. Probably this high K^+ concentration has a favorable influence on the conformation of various enzyme proteins [20]. Potassium ions can easily penetrate plant membranes (see Section Nutrient Uptake and Long-Distance Transport in Plants), which often leads to a depolarization of the membranes. Membrane depolarization, it is supposed, has a favorable effect on meristematic growth, photophosphorylation, aerobic phosphorylation, and phloem loading [21]. These basic processes are important for the long-distance transport of photosynthates, the synthesis of various organic compounds, and CO_2 assimilation.

The data in Table 5 show that with an increase of K^+ in alfalfa leaves (*Medicago sativa*), the CO_2 assimilation rate increased, while the mitochondrial respiration rate decreased [22]. In the case of low K, the respiration was about 2/3 of the CO_2 assimilation, while with high K the C gained by assimilation was about 11 times higher than the C lost by respiration. This typical behavior indicates that under the conditions of K^+ deficiency much of the stored carbohydrates must be respired in order to meet the ATP demand of the plant. Plants undersupplied with K^+ have therefore a low energy status. Such plants are highly susceptible to fungal attack, water stress, and frost damage.

Table 5. Relationship between K^+ concentration in the dry matter of alfalfa leaves, CO_2 assimilation, and mitochondrial respiration [22]

Concentration of K^+, mg/g	Carbon gain and loss, mg dm^{-2} h^{-1}	
	CO_2 assimilation	Mitochondrial respiration
13	11.9	7.56
20	21.7	3.34
38	34.0	3.06

Potassium is important in determining the osmotic pressure of plant fluids, and K^+-deficient plants are characterized by inefficient water use. Sodium ions may replace some K^+ functions, e.g., the less specific osmotic functions. Important counterions of K^+ in plant tissues are Cl^-, NO_3^-, and organic anions. The frequently observed favorable effect of Na^+ and Cl^- on plant growth is related to their osmotic functions.

Plants suffering from K^+ deficiency show a decrease in turgor, and under water stress they easily become flaccid. Plant growth is affected, and the older leaves show deficiency symptoms as necrosis beginning at the margins of tips and leaves. In K^+-deficient plant tissue, toxic amines such as putrescine and agmatine accumulate.

The most spectacular function of *magnesium* [7439-95-4] is its integral part in the chlorophyll molecule. Besides this function, Mg^{2+} is required in various other processes and, the Mg fixed in the chlorophyll molecule amounts only to about 20 % of the Mg present in green plant tissues. Magnesium is an essential ion in ribosomes and in the matrix of the cell nucleus. Here Mg^{2+} is bound by phosphate groups, since the Mg^{2+} is strongly electrophilic and thus attracts oxo complexes such as phosphate [23]. The magnesium ion activates numerous enzymatic reactions in which phosphate groups are involved. The activation is assumed to be brought about by bridging the phosphate group with the enzyme or with the substrate. This is an universal function of Mg^{2+} not only relevant for plant metabolism but also for practically all kinds of organisms.

Deficiency of Mg^{2+} affects chlorophyll synthesis: leaves turn yellow or red between the veins. The symptoms begin in the older leaves. Protein synthesis and CO_2 assimilation are depressed under Mg^{2+} deficiency conditions. Recent results [24] have shown that the yellowing of spruce needles in the Black Forest is due to a Mg^{2+} deficiency and can be cured by Mg^{2+} fertilizer application.

Calcium [7440-70-2] is the element of the apoplast (cell wall and “free space”) and of biological membranes. Here it is adsorbed at the phosphate head groups of membrane lipids, thus stabilizing the membranes [25]. Most of the Ca^{2+} present in plant tissues is located in the apoplast and in the vacuole, some in the mitochondria and in the chloroplasts, while the cytoplasm is extremely low in Ca^{2+} (10^{-7} to 10^{-6}M). The maintenance of this low cytoplasmic Ca^{2+} concentration is of vital importance for the plant cell [26]. Higher cytoplasmic Ca^{2+} concentrations interfere with numerous enzymatic reactions and may even lead to a precipitation of inorganic phosphates. This low Ca^{2+} concentration suffices to form a complex with calmodulin, a polypeptide of 148 amino acids. The Ca – calmodulin complex is a universal enzyme activator. The activation is brought about by allosteric induction.

Direct Ca^{2+} deficiency in plants is rare, since most soils are relatively rich in Ca^{2+}. Physiological disorders as a consequence of an insufficient Ca^{2+} supply of particular plant parts, however, occur frequently. Calcium is mainly translocated by the transpiration stream. Hence plant parts such as fruits, which mainly feed from the phloem and less from the xylem sap, may suffer from an insufficient Ca^{2+} supply. Shear [27] cites a list of 35 such Ca^{2+}-related disorders in fruits and vegetables. Two of the most important ones involve storage tissues and result in poor crop qualities [28]: *bitter pit* in apples, characterized by small brown spots on the surface, and *blossom-end rot* in tomatoes, a cellular breakdown at the distal end of the fruit, which is then susceptible to fungal attack.

Manganese [7439-96-5] is an integral part of the superoxide dismutase and of the electron donor complex of photosystem II. Manganese may activate enzymes in the same way as Mg^{2+} by bridging the phosphate group with the enzyme or the substrate. Deficiency of Mn^{2+} leads to the breakdown of chloroplasts. Characteristic deficiency symptoms are smaller yellow spots on the leaves and interveinal chlorosis. Manganese toxicity may occur, especially on flooded soils, because of the reduction and thus solubilization of manganese oxides. Toxicity symptoms are generally characterized by brown spots of MnO_2 in the older leaves surrounded by chlorotic areas [29].

Iron [7439-89-6] is an essential element for haem and ferredoxin groups. Iron deficiency leads to chloroplast disorders; the synthesis of thylakoid membranes is disturbed and the photochemical activity affected [30]. Iron deficiency is characterized by yellow leaves. The symptoms are at first visible in the younger leaves. There is evidence that the deficiency, mainly occurring in plants growing on calcareous soils, is not induced by an insufficient Fe uptake from the soil but by a physiological disorder in leaves, affecting the Fe distribution in the leaf tissue [31].

Iron toxicity can be a problem under reducing soil conditions, which prevail in flooded soils. Under such conditions iron(III) oxides are reduced and the iron is rendered soluble. This may increase the Fe concentration in the soil solution by a factor of 10^2 to 10^3 [32] so that plants may suffer from Fe toxicity, characterized by tiny brown spots on the leaves, which later may turn uniformally brown. Iron toxicity is known as “bronzing.”

Copper [7440-50-8] is an essential element of various enzymes, such as superoxide dismutase, polyphenol oxidases, plastocyanin of the photosynthetic transport chain, and cytochrome c oxidase, the terminal oxidase in the mitochondrial electron transport chain. Deficiency in Cu leads to pollen sterility and thus affects the fruiting of plants. Copper-deficient plants often are characterized by white twisted leaf tips and a tendency to become bushy.

Zinc [7440-66-6] is an integral part of carbonic anhydrase, superoxide dismutase, RNA polymerase, and various dehydrogenases. It is closely involved in the N metabolism of plants. In Zn-deficient plants, protein synthesis is hampered and free amino acids accumulate. There is evidence that Zn is involved in the

synthesis of tryptophan, which is a precursor of indole acetic acid, an important phytohormone. Zinc deficiency is characterized by short internodes, small leaves, and chlorotic areas in the older leaves. Frequently the shoots die off and the leaves fall prematurely.

Molybdenum [7439-98-7] is present in the nitrate reductase and in the nitrogenase system that catalyzes the bacterial fixation (reduction) of dinitrogen. Deficiency of Mo frequently appears first in the middle and older leaves as a yellowish green coloration accompanied by a rolling of leaf margins. Cruciferae species are particularly susceptible to Mo deficiency. The most well-known Mo deficiency is the “whiptail” of cauliflower. For further information on the physiology of plant nutrition, see [3], [23], [33].

2.2. Soil Science

2.2.1. *Soil Classes, Soil Types, and Parent Material*

According to SCHROEDER [34], “soil is the transformation product of mineral and organic substances on the earth's surface under the influence of environmental factors operating over a very long time and having defined organisation and morphology. It is the growing medium for higher plants and basis of life for animals and mankind. As a space-time system, soil is four dimensional.”

Soils are complex, quite heterogeneous, and may differ from each other considerably. Nevertheless, all soils have some common features. They possess a mineral, an organic, a liquid, and a gaseous component. In an ideal soil, the percentage proportions of these components are 45 %, 7 %, 23 %, and 25 %, respectively. The volumes of the liquid and gaseous components may change quickly. For example, in a water-saturated soil all pores are filled with water, and in a dry soil the soil pore volume is almost completely filled with air. The mineral and organic components contain plant nutrients and adsorb plant nutrients at their surfaces, and they are therefore of importance for the storage and retention of plant nutrients. The liquid phase of the soil is the soil solution. It contains dissolved plant nutrients and is the medium for the translocation of plant nutrients from various soil sites towards the plant roots. The gaseous soil component is essential for gas exchange, especially for the supply of plant roots with oxygen and for the release of CO_2 from the soil medium into the atmosphere.

For the description, comparison, and assessment of soils, a grouping according to general criteria is indispensable. There are two main grouping systems for soils: (1) soil classes or soil texture and (2) soil types. *Textural classes* are defined according to the particle size of soils. *Soil types* relate to the parent material of soils, to the pedological genesis, and to typical properties evident in the soil profile i.e., the horizontal layers of soils, called soil horizons.

Soil Classes. *Soil particle sizes* as a main characteristic of soil classes are grouped into four major groups as shown in Table 6. The major groups (sand, silt, and clay) are subdivided into coarse, medium, fine. Designation of the soil texture (soil class) depends on the percentage proportions of the sand, silt, and clay fraction in the total fine earth, which is sand + silt + clay. Soils in which the sand fraction dominates are termed *sandy soils*, soils consisting mainly of silt and clay are *silty clays*, and soils which contain all three fractions in more or less equal amounts are called *loams*. In the German terminology, abbreviations for the fractions are used (S = sand, U = silt, T = clay, L = loam). For example, if the major fraction is silt (U) and the next sand (S), the abbreviation is sU = sandy silt. Figure 1 shows the designations of the various soil classes according to the percentage proportion of the three main particle fractions.

Table 6. Particle size of soil fractions relating to soil texture

Diameter, mm	Designation	Abbrevation
> 2	pebbles, gravels	
0.06 – 2	sand	S
0.002 – 0.06	silt	U
< 0.002	clay	T

Figure 1. Diagram of soil textural classes, German system of SCHROEDER [34]

The vertical axis shows the percentage of silt, the horizontal the percentage of clay, and the dashed line the percentage of sand.

In the farmer's practice, sandy soils are called light soils, soils rich in clay heavy soils. This distinction relates to the force required to work (plough, cultivate) a soil. Soils rich in clay, but also silty soils, tend to compaction when dried and hence are heavy to work.

Although the grouping according to particle size is based on a physical factor, particle size is also associated with the chemical properties. This can be seen from Figure 2: the sand fraction consists mainly of quartz, which is a sterile material. Primary silicates (micas, feldspars) contain K, Ca, Mg, and other plant nutrients, which are released during the process of weathering. Clay minerals are less rich in plant nutrients than the primary silicates, but they possess large negatively charged surfaces that are of the utmost importance for the adsorption of plant nutrients and water.

Figure 2. Mineral composition of the sand, silt, and clay fractions [34]

The various soil particles form aggregates in which organic matter is also involved. This aggregation forming fine pores and holes in the soil is of relevance for soil structure. A good soil structure is characterized by a relatively high pore volume, ca. 50 % of the total soil volume. Soil structure depends much on the Ca saturation (see Cation exchange capacity). The richer the soil is in clay, the more important a good soil structure is.

Soil Type. Soil type is related to the parent material from which a soil is developed and from the history of development, which is much influenced by climate and vegetation. Main groups of parent material are igneous rocks, sedimentary rocks, and metamorphic rocks. Also organic matter may be the main parent material. Content of plant nutrients, capacity to store plant nutrients, soil pH, and the rooting depth depend much on the parent material, but are also influenced by soil development.

In the following, a limited number of important soil types are considered according to the FAO World Soil Classification. Besides this system there are other systems, e.g., the U.S. Soil Taxonomy. The FAO classification comprises 26 classes.

A distinction can be made between young soils and old soils. The latter are generally highly weathered, their inorganic material consisting mainly of quartz and iron aluminum oxide hydroxides. Such soils are characterized by poor cation retention capacity (cation exchange capacity), low pH values, and a high phosphate fixing power. This soil type, called ferralsol, is frequent in the tropics, whereas in moderate climates highly weathered soils belong mainly to the podsols.

Young soils may be derived from the sedimentation of rivers and oceans (fluvisols) or from volcanic ash (andosols). These soils are generally rich in plant

nutrients and thus form fertile soils. The most fertile soils belong to the black earths (chernozem). They are frequent in Russia, Central and East Europe as well as North America and are derived from loess. They are characterized by a neutral pH, by a well balanced content of clay and organic matter and by a deep rooting profile. They are naturally rich in plant nutrients and possess a high nutrient storage capacity. Soils in which the parent material loess is more weathered as compared with the chernozems belong to the luvisols. This soil type is common in Germany, Austria, and France where it represents the most fertile arable land. Gleysols are soils with a high water table, rendzinas are shallow soils derived from limestone, histosols are rich in only partially decomposed organic matter.

Under arid conditions salt may accumulate in the top soil layer. Solonchaks (white alkali soils) are saline soils with a pH of ca. 8 and with neutral anions as the most important anion component. Solonetz soils (black alkali soils) possess bicarbonate and carbonate as major anion component. Their pH is in the range 8 – 10. Crop growth on saline soils is extremely poor, and in many cases only a salt flora can grow under such conditions. This is particularly true for the solonetz soils.

For further information on soil texture and soil types, see [34-37], and the Soil Taxonomy of the Soil Conservation Service of U.S. Department of Agriculture [38].

2.2.2. *Nutrient Retention in Soils*

Nutrient retention is an important characteristic of fertile soil.

Cation Exchange. Cations are retained on soil colloids having a negative charge: the cations are bound at the surface of these particles by Coulomb forces. The most important cation species are Ca^{2+}, Mg^{2+}, K^+, Na^+, Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$, and H^+. This is represented in Figure 3. A distinction can be made between inorganic and organic soil colloids capable of cation adsorption. Inorganic particles belonging to the clay fraction are known as *secondary clay minerals* because they are mainly derived by weathering of primary minerals such as orthoclase, plagioclase, and particularly mica. Organic soil colloids capable of cation adsorption belong to the *humic acids*. The negative charge of the inorganic soil colloids originates from the so-called isomorphic substitution and from deprotonation. Isomorphic substitution is the replacement of Si^{4+} in the crystal lattice by Al^{3+}, Fe^{2+}, or Mg^{2+}, thus leading to a surplus of negative charge, because the anionic groups of the lattice are not completely balanced by Al^{3+}, Fe^{2+}, or Mg^{2+}. Such a negative charge is a permanent charge, in contrast to labile charges that result from deprotonation. Labile charges are typical for organic colloids (humic acids): carboxylic groups and acid hydroxylic groups of phenols may be protonated or not depending on the pH of the environment.

Figure 3. Schematic presentation of cations adsorbed to the negatively charged surface of a soil colloid

The secondary clay minerals are grouped into 1 : 1 clay minerals, in which a Si layer alternates with an Al layer, and 2 : 1 clay minerals, in which an Al layer is sandwiched by two Si layers. The most important representatives of the 1 : 1 clay minerals are the kaolinites. The 2 : 1 secondary clay minerals comprise the illite, transitional minerals, vermiculite, chlorite, and smectites (⟶ Clays). Most of these 2 : 1 clay minerals possess inner surfaces. They are therefore characterized by a high cation retention (= cation exchange) capacity.

These negatively charged soil colloids, often also called sorption complexes, function like a *cation exchanger*. Adsorbed cations can be replaced by other cation species. The cation exchange is stoichiometric. Adsorption and desorption depend on the concentrations of the cation species in the surrounding solution. If a soil colloid completely saturated by K^+ is exposed to increasing Ca^{2+} concentrations, for example, adsorbed K^+ is more and more replaced by Ca^{2+} until eventually the sorption complex is completely saturated by Ca^{2+} (Fig. 4). In soils, such exchange and equilibrium reactions are complex as numerous cation species and sorption complexes with differing preferences for particular cation species are involved. The principle, however, is that cations adsorbed by Coulomb forces at soil colloids equilibrate with free cations in the soil solution. Thus adding cations to a soil by fertilization, e.g., the application of a potassium salt, results in replacing adsorbed cations with the newly added cations until a new equilibrium is reached. The adsorbed cations are protected against leaching. but they are available to plant roots. The strength of cation adsorption increases with the the charge of the cation species and with the thinness of the hydration shell. Provided that there are no specific adsorption sites, the strength of cation adsorption follows Hofmeister's cation sequence:

$$Ca^{2+} > Mg^{2+} > K^+ > Na^+$$

Figure 4. Ca^{2+} – K^+ exchange, K^+ desorption brought about by increasing Ca^{2+} concentration

At equilibrium, cation-exchange reactions are a helpful tool for predicting the distribution of ions between the adsorbed and solution phases of the soil as the amounts of cations present are changed. When a soil saturated with potassium is placed in a NaCl solution, the following equilibration occurs:

$$K_{soil} + NaCl \rightleftharpoons Na_{soil} + KCl$$

The exchange equation for this reaction is

$$\frac{[Na](K)}{[K](Na)} = k_1$$

Brackets refer to ions on the exchange site and parenthesis to the activity of ions in the solution. Since the proportionate strength of adsorption of the ions varies with the exchange site, values for k_1 differ for different exchange materials.

The divalent/monovalent system, which almost represents the situation in the soil, with K^+, Ca^{2+}, and Mg^{2+} as the dominant exchangeable cations, is more complex. The following equation, developed by GAPON [39], is widely used to describe monovalent/divalent exchange:

$$\frac{[K](Ca)^{1/2}}{[Ca](K)} = k_1$$

Cation exchange capacity (CEC) is defined as the quantity of cation equivalents adsorbed per unit soil or clay mineral. In Table 7 the exchange capacities of some soil classes are shown. The exchange capacity of the organic soil appears high if it is based on unit weight of soil. A more realistic picture is obtained, however, when the exchange capacity is based on soil volume, since under field conditions it is soil volume, not soil weight, that is related to a crop stand. Table 8 shows the cation exchange capacities of some important clay minerals and of humic acids in relation to the surface of these particles.

Table 7. Cation exchange capacity based on soil weight and soil volume as well as the specific weight of some soil classes

Soil class	Specific weight, kg/L	Cation exchange capacity *

		cmol/kg	cmol/L
Sandy soil	1.5	3	4.5
Loam	1.5	15	22.5
Clay soil	1.5	30	45.0
Organic soil	0.3	75	22.5

* cmol = centimole.

Table 8. Cation exchange capacity and inner and outer surfaces of some soil colloids

	Total surface, m^2/g	Inner surface, %	Cation exchange capacity, mol/kg
Kaolinite	20	0	10
Illite	100	0	30
Smectite	800	90	100
Humic acids	800	0	200

The cation exchange capacity of kaolinites and particularly of humic acids depends much on the pH of the medium. At low pH, most groups are protonated and hence the exchange capacity is low. Increasing soil pH, e.g., by liming, increases the cation exchange capacity if kaolinites and humic acids are the dominating exchange complexes.

Cation saturation of negatively charged soil colloids has some impact on soil structure, which is defined as the arrangement of soil particles into aggregates. High percentage of adsorbed Ca^{2+} favors the formation of aggregates. In well structured soils, such as in chernozems, 70 to 80 % of the total cation exchange capacity is occupied by Ca^{2+}. In acid solids, H^+ and Al cations (Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$) and in saline soils Na^+ and Mg^{2+} are the dominating cation species adsorbed to soil colloids.

Anion Exchange. Soil particles may also adsorb anions. The adsorption occurs at the OH groups of aluminum and iron oxides as well as of some clay minerals. One may distinguish between a nonspecific adsorption and a specific anion adsorption. The nonspecific anion (A^-) adsorption originates from protonated hydroxylic groups.

Protonation depends on soil pH and is particularly high under acid conditions. Hence nonspecific anion adsorption only plays a role in acid soils.

The specific anion adsorption is a ligand exchange. This is, for example, the case for phosphate. In step 1 $H_2PO_4^-$ replaces OH^-, resulting in a *mononuclear bond* between the phosphate and the iron oxide. In step 2, a further deprotonation of the phosphate occurs, followed by a second ligand exchange (step 3) to form a *binuclear bond* between the surface of the iron oxide and the phosphate.

The final structure is supposed to be very stable, and the phosphate so bound is hardly available to plant roots. This reaction sequence explains why anion (phosphate) adsorption is promoted under low pH conditions. In mineral soils with pH < 7, the adsorbed phosphate represents a major phosphate fraction. Increasing the soil pH, e.g., by liming, increases phosphate availability [40]. The relationship between free and adsorbed anions can be approximately described by the Langmuir equation:

$$A = A_{max}\frac{kc}{1+kc}$$

A = surface concentration of adsorbed anions
A_{max} = maximum surface concentration
c = concentration of free anion
k = constant related to adsorption energy, the adsorption strength increasing with k

Adsorption strength depends also on anion species decreasing in the order [41]:

$$\text{phosphate} > \text{arsenate} > \text{selenite} = \text{molybdate} > \text{sulfate} = \text{fluoride} > \text{chloride} > \text{nitrate}$$

Borate and silicate may also be adsorbed, but only at high pH. Under these conditions, boric acid and silicic acid may form anions according to the following equations:

$$H_3BO_3 + H_2O \rightarrow B(OH)_4^- + H^+$$

$$H_2SiO_3 + H_2O \rightarrow H_3SiO_4^- + H^+$$

This is why in neutral to alkaline soils boron can be strongly adsorbed (fixed) by soil particles, which may lead to boron deficiency in plants. The formation of a

silicate anion can improve phosphate availability since $H_3SiO_4^-$ and phosphates compete for the same ligands at anion-adsorbing surfaces.

2.2.3. *Soil pH, Buffer Power, and Liming*

Proton concentration (pH) is of vital importance for all living organisms and also has an impact on soils and soil constituents. High H^+ concentrations (pH<4) attack soil minerals, dissolving metal cations out of the crystal lattice, and eventually lead to mineral degradation. Under low soil pH conditions (pH<5), bacterial life is suppressed while fungal life is relatively favored, which affects the decomposition of organic matter. Low soil pH (pH < 4) also affects root growth.

In many cases, however, it is not so much the H^+ but the toxic level of soluble Al species and Mn^{2+} associated with low pH conditions that considerably hamper root development and plant growth. A decrease in soil pH increases the solubility of aluminum oxide hydroxides and maganese oxides considerably. Under acid soil conditions Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$ are dissolved in the soil solution or adsorbed to soil colloids. Of the three Al species, $Al(OH)^{2+}$ is considered to be the most toxic. *Aluminum toxicity* of plants is characterized by poor root growth: root tips and lateral roots become thickened and turn brown [42]. In the cell, Al interferes with the phosphate turnover and may even be adsorbed on the DNA double helix.

A distinction is made between the *actual acidity*, which is determined by the H^+ concentration in the soil solution, and the *potential acidity*, which is determined by both the H^+ of the soil solution and the adsorbed H^+. The actual acidity is measured by hydrogen-ion electrodes; the potential acidity, by titration with a base. Titration includes the Al species, which also consume OH^-

$$Al^{3+} + OH^- \rightarrow Al(OH)^{2+}$$

$$Al(OH)^{2+} + OH^- \rightarrow Al(OH)_2^+$$

$$Al(OH)_2^+ + OH^- \rightarrow Al(OH)_3 \text{ (gibbsite)}$$

Potential acidity may be high in Al-rich soils as well as in soils with a high cation exchange capacity. Such soils are characterized by a high *hydrogen-ion buffer power*: a pH change in the soil solution requires a relatively large amount of H^+ or OH^-.

In soils, different buffer power systems can be distinguished. Soils containing carbonates are buffered according to the following equation:

$$CaCO_3 + 2\,H^+ \rightarrow Ca^{2+} + H_2O + CO_2$$

Reaction may be promoted by the presence of CO_2 originating from root and microbial respiration.

$$CaCO_3 + CO_2 + H_2O \rightarrow Ca(HCO_3)_2$$

$$Ca(HCO_3)_2 + 2\,H^+ \rightarrow Ca^{2+} + 2\,H_2O + 2\,CO_2$$

At lower pH levels soils are buffered by adsorbed cations (Fig. 5) and by Al complexes, e.g.,

$$Al(OH)_3 + H^+ \rightarrow Al(OH_2)^+ + H_2O$$

Figure 5. Principle of hydrogen-ion buffering by adsorbed cations

Soil acidification results from different processes. Plant roots extrude H^+; net release of H^+ is especially high when plants are fed with NH_4^+, while NO_3^- nutrition results in a net release of OH^-. Leguminous species living in symbiosis with *Rhizobium* extrude H^+ at particularly high rates from their roots. Microbial oxidation of organic N, organic S, and elementary S leads to the formation of strong acids, such as HNO_3 and H_2SO_4, which have a marked acidifying effect on soils. Also SO_2 and NO_x as gases as well as the acid rain formed by these oxides have an acidifying effect. In Central Europe these pollutants carry ca. 3 – 5 kmol H^+ $ha^{-1}a^{-1}$ into soils.

Under anaerobic soil conditions, e.g., after flooding, protons are consumed by the reduction of Fe^{III} and Mn^{III} or Mn^{IV} as well as by the microbial reduction of NO_3^- (denitrification):

$$2\,NO_3^- + 10\,e^- + 12\,H^+ \rightarrow N_2 + 6\,H_2O$$

Some species of *Azalea, Calluna*, *Vaccinium*, and also tea (*Camellia sinensis*) are able to grow on acid habitats. These species can mask the Al with phenols and organic acids and thus avoid Al toxicity. Rye, potatoes, oats, and lupines tolerate weakly acid soils, whereas beets (*Beta vulgaris*), barley, rape, and most leguminous crops prefer more neutral soils. Wheat takes an intermediary position with regard to soil pH. In the case of leguminous crops, it is not so much the crop itself, rather it is the *Rhizobium* bacteria living in symbiosis with the crop that are affected by low soil pH. The mulitplication of the *Rhizobium* in the soil is depressed by soil acidity.

Low pH levels can be easily overcome by *liming*, the application of alkaline materials, mainly Ca/Mg oxides, carbonates, and silicates. They react with soil acidity as follows:

$$CaO + 2\,H^+ \rightarrow Ca^{2+} + H_2O$$

$$CaCO_3 + 2\,H^+ \rightarrow H_2O + CO_2 + Ca^{2+}$$

$$CaSiO_3 + 2\,H^+ \rightarrow H_2O + SiO_2 + Ca^{2+}$$

The quantity of lime required depends on the soil pH level and the buffer power. The lower the pH and the higher the buffer power, the more lime required.

Soil acidity is mainly a problem in humid zones, where the H^+ formed in the upper soil layer replaces the adsorbed metal cations (Ca^{2+}, Mg^{2+}, K^+), which are then leached. Under arid conditions, salts may accumulate in the top soil layer. If a major part of the anions accumulated are HCO_3^- and CO_3^{2-} (solonetz soils), high soil pH levels prevail, which affect plant growth and soil structure considerably. Such soils can be meliorated by heavy applications of elementary sulfur. Under aerobic conditions the S is oxidized to H_2SO_4 by soil microorganisms. The strong acid neutralizes the HCO_3^- and CO_3^{2-}

$$H_2SO_4 + 2\,HCO_3^- \rightarrow 2\,H_2CO_3 + SO_4^{2-} \rightarrow 2\,H_2O + 2\,CO_2 + SO_4^{2-}$$

$$H_2SO_4 + CO_3^{2-} \rightarrow SO_4^{2-} + H_2CO_3 \rightarrow H_2O + CO_2 + SO_4^{2-}$$

2.2.4. *Soil Water – Plant Relationships*

Plants continuously require water that is taken up from the soil by roots and transported from them to the upper plant parts, particularly to the leaves. From here water is released into the atmosphere. This last process is called *transpiration*. Water in the plant tissues is required to maintain optimum cell turgor, which is crucial for most metabolic processes.

Plants frequently have to overcome long dry periods during which they must feed from the soil water. Very crudely, the soil can be considered as a sponge that

can store water in its pores and holes. The storage water in the soil must be retained against gravitation. The forces responsible for this retention are adsorption and capillary forces by which the water is sucked to the surface of the soil particles. This suction force can be considered as a negative pressure, and hence the strength of water binding in soils is measured in Pascals (Pa), the unit for pressure. The strength of water binding in soils is termed *water potential* (in older terminology, water tension). The higher the strength, the lower (more negative) the soil water potential. Water potentials in soils range from 0 to -1×10^6 kPa. Generally, however, soil water potentials of – 10 to – 1500 kPa prevail.

The total amount of water that can be adsorbed by a soil (all pores and holes filled with water) is called maximum water capacity. This is of minor importance; more relevant is the water quantity that can be retained against the gravitation force, the *field capacity*. Not all water of the field capacity fraction is available to plant roots. A proportion of the field capacity water is so strongly adsorbed that it can not be taken up by the roots. For most plant species this is water with a water potential < – 1500 kPa: at such a low water potential, plants wilt. Therefore, this critical water potential is also called *wilting point*. The soil water fraction not available to plants is called *dead water*. The *available soil water* thus equals the difference between the field capacity and dead water.

Soils differ much in their capacity to store water. The higher the clay content of a soil, the larger the total surface of soil particles, and the more water that can be adsorbed. The water storage capacity of soils increases with the clay content. On the other hand, the water molecules are strongly adsorbed to the surface of clays and therefore the fraction of dead water increases with the clay content. For this reason, generally medium textured soils (loamy soils), and not the clay soils, possess the highest storage capacity for available soil water. Besides soil texture, also soil structure and the rooting depth of the soil profile determine the storage capacity for available soil water.

An important criterion of available soil water is the relationship between the percent water saturation of the soil and the water potential. This is shown in Figure 6 for a sandy, a loamy, and a clay soil. The section between field capacity (– 10 kPa) and the wilting point (– 1500 kPa) is the highest for the loamy soil.

Figure 6. Relationship between the soil water content and the soil water potential and the resulting available water (AW) for three soil classes

Field capacity is –10 kPa; wilting point is – 1500 kPa.

The capability to use soil water economically differs considerably among plant species. A measure of this capability is the transpiration coefficient, the water quantity in kg (or L) required for the production of 1 kg plant dry matter:

Sorghum	277
Maize	349
Sugar beet	443
Spring wheat	491
Barley	527
Potatoes	575
Oats	583
Spring rye	634
Red clover	698
Flax	783
Alfalfa	844

Water loss under a vegetation cover results from evaporation (water release from the soil to the atmosphere) and transpiration (water release of the plant to the atmosphere). Evaporation is unproductive, transpiration productive. The relation between the two depends on plant nutrition, as can be seen in Table 9, which shows the favorable effect of N fertilizer on the productive use of soil water [43].

Table 9. Relationship between N fertilizer rate, grain yield of barley, evaporation, and transpiration [43]

Nitrogen fertilizer rate, kg/ha	Grain yield, t/ha	Transpiration,* L/m^2	Evaporation,* L/m^2
30	1.02	85	235
125	1.65	121	278
225	2.69	217	212

* Transpiration and evaporation in liters per square meter of soil surface.

2.2.5. *Organic Matter of Soils and Nitrogen Turnover*

Organic matter of soils differs considerably. Soils can be classified according to the content of organic carbon in the soil (g/kg):

Low	<5
Medium low	5 – 10
Medium	10 – 20
High	20 – 40
Rich	40 – 80
Muck	80 – 150
Peat	>150

Soils with an organic carbon content of 50 g/kg are termed organic soils, in contrast to mineral soils. Enrichment of organic matter in soils depends on location and climatic conditions. Low temperature and a lack of oxygen favor the accumulation of organic matter in soils because these conditions hamper breakdown by soil microbes. Therefore, under cold continental climate conditions (frost, long winters) and under hydromorphic soil conditions (swamps, moors, bogs), organic matter accumulates.

The fertility status of organic soils differs considerably. Moors located on the tops of mountains are generally poor in nutrients, especially in N and K, since they are fed mainly from rain. Moors in lowland fed from rivers and streams may be rich in plant nutrients, especially in N. The C : N ratio of the organic matter and soil pH are suitable indicators of the fertility status. Fertile soils possess C : N ratios of ca. 20 in their organic matter and pH values in the weak acid to weak alkaline range. Acid organic soils (highland moors) have much higher C : N ratios, ca. 50 or more in their organic matter. The C : N ratio has direct impact on the decomposition of organic N by soil microbes; the higher the ratio the lower the net release of mineral N by microbial activity.

Nitrogen turnover in soils is related not only to biological processes but also to physicochemical processes. In addition, there is a rapid exchange of N between the biosphere, the soil, and the atmosphere. The main processes of this nitrogen cycle are shown in Figure 7. Inorganic nitrogen, mainly NO_3^- and NH_4^+, including fertilizer N, can be easily assimilated by higher plants as well as by microbes (fungi, bacteria). Also dinitrogen (the N_2 of the atmosphere) can be reduced to NH_3 by some soil bacteria. The N_2 fixation capacity of the so-called free living bacteria, mainly species of *Azotobacter, Beijerinckia, Azospirillum,* and some species of the Cyanobacteria (*Anabaena, Nostoc, Rivularia*) is moderate, amounting to ca. 5 – 50 kg $ha^{-1}a^{-1}$. Symbiontic N_2-fixing bacteria, mainly species of *Rhizobium* and *Actinomyces*, have a fixation capacity about 10 times higher: for pulses (grain legumes) 50 – 100 kg/ha per growth period and for forage legumes even 200 – 500 kg $ha^{-1}a^{-1}$. They are of utmost importance in the N turnover and N availability in soils.

Figure 7. N cycle in nature. Transfer of N between soil, plant, and atmosphere

Inorganic nitrogen (N_2, NH_4^+, NO_3^-) assimilated by living organisms is mainly used for the synthesis of proteins, amino sugars, and nucleic acids. As soon as these organisms die, the organic N can be attacked by other microorganisms, which are able to convert the organic N into an inorganic form, a process called nitrogen mineralization. This starts with ammonification, and under aerobic conditions and favorable soil pH ammonification is followed by nitrification in the sequence:

$$\text{Organic N} \rightarrow NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$$

Ammonification is carried out by a broad spectrum of heterotrophic organisms; nitrification only by a small number of autotrophic bacteria [44]. The microbial oxidation of NH_4^+ to NO_2^- and NO_2^- to NO_3^- requires oxygen and hence proceeds only under aerobic conditions. The oxidation of NH_4^+ to NO_2^- is brought about by species of *Nitrosomonas, Nitrosolobus,* and *Nitrospira*, oxidation of NO_2^- to NO_3^- by species of *Nitrobacter*. They all require weak acid to neutral soil conditions; in acid soils nitrification is more or less blocked.

Ammonium ions produced by microbial breakdown of organic N, including urea, as well as NH_4^+ fertilizer can also be fixed by 2 : 1 clay minerals. In this form, NH_4^+ is protected against nitrification and leaching, but, depending on the type of clay minerals, may still be available to plant roots [45]. This fixed NH_4^+ fraction is of major significance for plant nutrition in soils derived from loess.

The concentration of ammonium ion in the soil solution is governed by the equilibrium

$$NH_4^+ \rightleftharpoons NH_3 + H^+ \text{pK} = 9.25$$

At pH < 6, there is virtually no NH_3 present; with an increase in pH the deprotonation of NH_4^+ increases, and so does the risk of NH_3 loss by volatilization. In alkaline and calcareous soils considerable amounts of N can thus be lost by the soil system [46]. High losses of NH_3 may also occur from the application of slurries, which generally have an alkaline pH [47].

Ammonium as well as NO_3^- are taken up by plant roots at high rates, and vigorous crop stands can deplete the NO_3^- concentration in the soil to a great extent. Nitrate is very mobile in soils since it is virtually unadsorbed on soil colloids. It can be leached by rainfall to deeper soil layers or even into the ground water (see Section Gains and Losses of Plant Nutrients). Nitrate losses may also occur under anaerobic soil conditions, for some bacterial species are able to use the oxygen of the NO_3^- as e^- acceptor for respiration. Nitrate is thus reduced to volatile NO, N_2O, and N_2 [49]:

$$NO_3^- \rightarrow NO_2^- \rightarrow NO_{(g)} \rightarrow N_2O_{(g)} \rightarrow N_{2(g)}$$

This process, brought about mainly by species of *Pseudomonas*, *Alcalignes*, *Azospirillum*, *Rhizobium*, and *Tropionibacterium*, is called denitrification. It may cause considerable soil N losses particularly in flooded rice soils, in which anaerobic conditions prevail [50].

Loss of NO_3^- by leaching or denitrification can be reduced by blocking the NO_2^- formation by application of nitrification inhibitors such as Nitrapyrin (2-chloro-6-trichloromethylpyridine), AM (2-amino-4-chloro-6-trimethylpyrimidine), or terrazole (5-ethoxy-3-trichloromethyl-1,2,4-thiadizole). There are also some natural compounds that are nitrification inhibitors [51]. The most important is neem, which occurs in the seeds of *Azadirachta indica*, a tree common in the tropics.

Some of the organic N in the soil may be incorporated into a very stable organic form. This nitrogen, which mainly occurs in humic acids, is hardly mineralized. In most soils the humus-N fraction is by far the largest, comprising 80 – 90 % of the total soil N. It is of great importance for soil structure, but has hardly any relevance as a nutrient reserve.

The fraction of hydrolyzable soil N can be mineralized and thus may serve as a source for N absorbed by plants. The most important fraction in this respect is the N of the biomass, which comprises ca. 40 – 200 kg/ha, thus only a small fraction of total soil N, which may be 2000 – 8000 kg/ha in arable soils.

2.3. Nutrient Availability

2.3.1. *Factors and Processes*

From the total amount of N present in the soil, only a small proportion can be made available for plants (see above). This is also true for other plant nutrients. For example, in a clay-rich soil ca. 200 000 kg K^+ may be present in 1 ha within the rooting depth of 80 – 100 cm, but only 1 % may be available to plant roots.

Plant nutrient availability depends on physicochemical and biological factors. A young root pushing into a soil directly contacts only a small amount of macronutrients, which would contribute only a few percent of the total nutrient demand. By far the greatest proportion of nutrients (NO_3^-, NH_4^+, K^+, Ca^{2+}, Mg^{2+}) required by the plant must be transported towards the plant roots. This transport can be brought about by mass flow and/or diffusion. In *mass flow*, the nutrients are moved with the water flow from the soil towards the roots. Therefore mass flow depends much on water uptake and transpiration conditions. At zero transpiration (100 % relative humidity, rainy, or foggy weather) mass flow is also zero. Mass flow plays a major role for the transport of Ca^{2+}, Mg^{2+}, and also for NO_3^- in cases where the NO_3^- concentration of the soil solution is high, e.g., after fertilizer application.

Nutrients that are taken up at high rates by plant roots (K^+, NH_4^+; NO_3^-, phosphate) but that have relatively low total concentration in the soil solution are mainly transported by *diffusion*. Uptake of nutrients by roots decreases the nutrient concentration near the root surface and establishes a concentration gradient, which drives the diffusive flux of nutrients from the soil towards the plant roots. Absorbing roots thus act as a sink for plant nutrients. Typical depletion profiles are shown in Figure 8 for phosphate [52]. Phosphate and K^+ concentrations in the soil solution at the root surface may be as low as 1 μM, whereas in the bulk soil solution concentrations of 50 to 300 μM phosphate and 500 to 1000 μM K^+ may prevail. Fertilizer application increases the nutrient concentration of the soil solution and hence the concentration gradient that drives the nutrients towards the roots. Therefore, the level of the nutrient concentration in the bulk soil solution is an important factor of nutrient availability.

Figure 8. Phosphate depletion around a corn root: P concentration in the soil solution as a function of the distance from the root surface [52]

Diffusive flux and mass flow in the soil depend much on soil moisture. The dryer a soil, the smaller the water cross section (the size of soil pores that are still filled with water) and the more the nutrient flux is hampered. Therefore, soil moisture is another important factor of nutrient availability [53]. A third important factor of nutrient availability is the *nutrient buffer power* of a soil, a factor of particular relevance for phosphate, K^+, and NH_4^+. Here buffer power means the capability of a soil to maintain the nutrient concentration level in the soil solution (in analogy to the hydrogen-ion buffer power, see Section Soil pH, Buffer Power, and Liming). In well-buffered soils nutrients absorbed from the soil solution by roots are replenished by nutrient desorption, e.g., by cation exchange.

The most important biological factor for nutrient availability is root growth [54]. For most plant nutrients, only the soil volume around the root can be exploited by the plant. For phosphate the depletion zone extends only a few millimeter from the root surface and depends much on the length of root hairs, as can be seen from Figure 8. For K^+ and NH_4^+, the depletion zone is more extended, ca. 1 – 4 cm from the root surface. Root mass, root length, and root hairs therefore are of great importance for the portion of soil volume that can be exploited by a crop stand.

Roots excrete organic materials such as organic acids, sugars, and slimes from which bacteria feed. As a result, the bacterial colonization in the rhizosphere (the volume around the root) is much denser than in the soil apart from the roots. These bacteria are involved in the N turnover, e.g., for the N_2 fixation of free-living bacteria and for denitrifying bacteria [55].

Proton excretion of roots affects bacterial activity in the rhizosphere, the dissolution of calcium phosphates, and the cation exchange. Net proton release of plant roots is strongly affected by the type of N supply. Ammonium nutrition results in a high net release of H^+, nitrate nutrition in release of OH^- and HCO_3^-. Leguminous species living in symbiosis with *Rhizobium* are known for a high H^+ release by roots and therefore have a strong acidifying effect on soils.

Nutrient deficiency, e.g., phosphate or Fe deficiency, also increases net release of H^+, which may contribute to the dissolution of iron oxides and calcium phosphates. The release of avenic acid and mugineic acid by plant roots is of particular importance for the mobilization of Fe in the rhizosphere [56].

Plant growth may be enhanced after infection with mycorrhizal fungi, which leads to increased nutrient uptake due to increases in the effective absorptive surface of the root, mobilization of sparingly available nutrient sources, or excretion of ectoenzymes or chelating compounds. Furthermore, mycorrhizal fungi may protect roots from soil pathogens [57] and and in this way enhance root growth and nutrient acquisition of the host plant. This is particularly important when considering the nutrition of plants with immobile nutrients such as phosphorus, as fungal hyphae are known to absorb P and translocate it into the host plant [58].

2.3.2. *Determination of Available Plant Nutrients in Soils*

The level of available plant nutrients in soils can be assessed by means of plant analysis and soil analysis. In the case of *plant analysis*, the nutrient content of a particular plant organ at a certain physiological stage may reflect the nutritional status of the plant, hence also the nutrient status of the soils [59]. Such diagnostic plant analysis is particularly common for perennial crops, including fruit trees and forest trees.

In *soil analysis*, soil samples are extracted with special extractants. The quantity of nutrients extracted reflects the level of available nutrients in the soil. Numerous soil extractants have been developed. In Central Europe the DL method (double lactate method) and the CAL method (calcium acetate lactate method) are widely used for the determination of available soil K and P. In the Netherlands, available P is extracted by water (P-water method). In the United States, the Olsen method (extraction with NH_4F + HCl) is used for the determination of available soil phosphate [60]. Ion-exchange resins are also useful tools for the determination of available plant nutrients [61].

Of particular interest is the determination of available soil N early in spring before the first application of N fertilizer. Mineral N (NO_3^-, exchangeable NH_4^+) is extracted with a $CaCl_2$ or K_2SO_4 solution [62]. This technique, called the N_{min} method, provides reliable information on the level of directly available soil N. The easily mineralizable N in the soil, which frequently is the important fraction for the release of available N during the growth period, is not obtained by the N_{min} method.

Electro-ultrafiltration (EUF method) has been used for the determination of available soil nutrients [63]. This method uses an electric field to separate nutrient fractions from a soil suspension. Most plant nutrients can be extracted. The advantage of this method is that, besides inorganic nitrogen, the readily mineralizable organic N fraction is extracted [64].

In the last decade S has attracted interest as a plant nutrient. Numerous procedures have been proposed for the determination of plant-available S in soils. The procedures include extraction with water, various salts and acids, and S mineralization by incubation [65].

The relationship between soil analysis data and the response of crops to fertilizer application is not always satisfying since other factors may interfere, such as rooting depth, root morphology, soil moisture, and particularly the clay content. These factors should be taken into consideration in interpreting soil test data.

2.4. Physiology of Plant Nutrition

2.4.1. *Nutrient Uptake and Long-Distance Transport in Plants*

Oxygen and CO_2 are mainly taken up by aboveground plant parts. The process of uptake is a diffusion of CO_2 and O_2 into the plant tissue. For the entry of these gases into the plant, the stomata are of major importance. Water and other plants nutrients are mainly absorbed from the soil solution. The rate of nutrient uptake increases with the concentration of the particular nutrient in the soil solution, the rate of uptake leveling off at higher soil-solution concentrations.

Plant nutrients in the soil solution, mainly present in ionic form, diffuse into the root tissue. The outer plasma membrane of the cells (plasmalemma) is a great diffusion barrier. The transport of nutrients across this barrier is the proper process of ion uptake. This transport is not mere diffusion, but is related to specific membrane components and to metabolic processes that allow selective uptake of the plant nutrients, which is often associated with an accumulation of the nutrient in the cell. For example, the K^+ concentration in the cell (cytoplasm) may be higher by a factor of 10^2 – 10^3 than the K^+ concentration in the soil solution.

Nutrient uptake is initiated by an enzyme located in the plasma membrane called ATPase (ATP hydrolase). Its substrate is ATP. Hydrolyzation of ATP results in the splitting of H_2O into H^+ and OH^-, from which the latter remains in the cytosol of the cell while H^+ is extruded into the outer medium (Fig. 9). Thus an electrochemical potential is created between the two sides of the membrane. The proton motive force (p.m.f.) obtained in this way is described by the following equation [66]:

$$\text{p.m.f.} = -50\,\Delta\text{pH} + \Delta\varphi \quad \varphi = \text{electrical charge}$$

Figure 9. Scheme of plasmalemma-located ATPase, hydrolyzing ATP and pumping H^+ into the apoplast (proton pump)

The p.m.f. is the driving force for ion uptake. Cations are directly attracted by the negatively charged cell. Since the plasma membrane, however, represents a strong barrier, the entry of cation species must be mediated by particular carriers and ion channels. Little is known about these carriers and channels in plant membranes. These are assumed to be ionophores like valinomycin, nonactin, or gramicidin, which bind selectively to cation species and hence mediate a selective cation transport across the membrane. Such a type of carrier transport is shown in Figure 10. The carrier is hydrophobic and therefore quite mobile in

the membrane, which consists mainly of lipids. At the outer side of the membrane it combines selectively with a cation species, e.g., K^+. The cation carrier complex then diffuses to the inner side of the membrane, where the K^+ is released. Release and combining with K^+ depend on the electrochemical difference between the two sides of the membrane. High K^+ concentration and a positive charge favor the combining process; low K^+ concentration and a negative charge favor the release of K^+. Net transport rate becomes zero as soon as the electrochemical equilibrium is attained, which is governed by the Nernst equation:

$$E = \frac{RT}{zF} \ln \frac{a_o}{a_i}$$

E = electrical potential difference between the two sides of the membrane
F = Faraday constant
z = oxidation state of the cation
a_o = activity of the cation species in the outer solution
a_i = activity of the cation species in the inner solution

Figure 10. Scheme of K^+ carrier transport across the plasmalemma

The uptake of anions (NO_3^-, $H_2PO_4^-$) is also assumed to be driven by the plasmalemma-located ATPase. The anions presumably form protonated carriers at the outer side of the membrane and then are selectively tranported across the membrane. The protonated carrier – anion complexes are positively charged. Hence the electropotential difference between either side of the plasmamembrane represents the driving force for anion uptake.

Ion absorbed by cells of the root cortex are translocated via the symplasm in centripetal direction towards the central cylinder, where they are secreted into the xylem vessels. The actual process of this secretion is not yet understood. In the xylem the ions are translocated to the upper plant parts with the transpiration stream. They thus follow the vascular system of the plant and are distributed along the major and minor vein system of leaves from where they diffuse into the pores and intercellular spaces of cell wall (apoplast). The transport from the apoplast across the plasmamembrane into the cytoplasm of leaf cells is a process analogous to the nutrient uptake of root cells.

Some plant nutrients, such as N, P, K, and Mg, but not Fe and Ca, may also be translocated against the transpiration stream via the phloem tissue. These nutrients therefore may be transported from the tops to the roots or from older leaves to younger leaves.

2.4.2. *Effect of Nutrition on Growth, Yield, and Quality*

Meristematic growth requires plant nutrients: N and P for the synthesis of proteins and nucleic acids, K and Mg for the activation of enzymes and for membrane potentials, and all the other nutrients for various processes. The quantities required differ greatly but for practical purposes mainly N, K, and P, in some cases also Mg and Ca, limit plant growth. The growth rate is controlled by the nutrient with the lowest availability (LIEBIG's law of minimum). Application of this particular nutrient results in a growth response. This response is not linear, but rather follows a saturation type of curve (Fig. 11). Also crop yields as a function of increasing rates of fertilizer applicaton reflect this curve, which is also called the *Mitscherlich curve* since MITSCHERLICH [67] investigated these relationships extensively. The curve is described by the following equation:

$$\log (A - y) = \log (A - cx)$$

A = maximum yield
y = obtained yield
x = growth factor, e.g., fertilizer rate
c = constant

The term ($A - y$) is the increment that is required to attain the maximum yield. This increment becomes smaller as the variable x (growth factor) becomes greater. Such growth factors include not only plant nutrients, including CO_2, but also light intensity and temperature. The growth response obtained by these factors also follows the saturation type of curve shown in Figure 11.

Figure 11. Mitscherlich curve, response curve of diminishing increments (i) with each further unit of growth factor

Growth and metabolic processes in plant tissues depend not only on the rates of plant nutrients supplied but also on the ratio in which the nutrients are provided. If the N supply is relatively high as compared with the supply of other nutrients, the synthesis of N-containing compounds, such as amino acids and proteins, is promoted. This may have a favorable effect on the protein synthesis in grains of cereals and hence improve their baking quality and their nutritional value. In grains for malting purposes and in particular barley, however, low protein content and high starch content are required. In this case, relatively high N rates have a detrimental effect on grain quality. An analogous case is the sugar beet, which should be high in sugar and low in N-containing compounds, especially amino acids. Relatively high N supply favors the synthesis of vitamins of the vitamin B group and the synthesis of carotenes in green plant tissue but has a negative effect on the content in vitamin C. High N rates may also increase the sensitivity of leaves and culms to fungi attack.

Phosphate and especially K^+ have a favorable impact on the energy status of plants. A relatively high supply of both nutrients promotes the synthesis of carbohydrates and the development of cell wall material, which increases the resistance against fungi attack.

2.5. Nutrient Balance

2.5.1. *Gains and Losses of Plant Nutrients*

In order to maintain the level of available plant nutrients in soils, the quantity of nutrients lost from the soil must be replenished. Nutrients may be lost by harvesting of plant material, leaching, transition into a non-available form in the soil, and volatilization. Nutrient gains result from fertilizer application, soil weathering, rainfall, and microbial dinitrogen fixation (see Section Organic Matter of Soils and Nitrogen Turnover). In most soils, weathering provides enough of those nutrients that are only required in minor amounts, such as Fe, Mn, Cu, Zn, Mo, and B. Young soils being rich in primary minerals also may weather appreciable amounts of Mg, K, and phosphate. Generally, the contribution of plant nutrients released by weathering is more important if the yield level is lower. Up to the mid-1980s, sulfur supply to crops was to a large extent brought about by SO_2 in the atmosphere and by SO_2 dissolved in precipitation. However, in the last two decades increased global environmental concern has prompted reductions in SO_2 emissions, which in past years were beneficial for crop growth in many countries [68]. With the reduction in the sulfur supply from atmospheric emissions, the greater use of high-analysis S-free fertilizers, new high-yielding crop varieties, and declining use of sulfur as a fungicide, sulfur deficiency became widespread in various parts of the world.

The quantity of nutrients taken up by crops depends mainly on the yield level and on the kind of plant organs. For a rough calculation of *nutrient uptake by crops* the following figures may be used:

1 t of grain (cereals) contains	
20 – 25	kg N
5	kg K
4	kg P
1 t of dry matter of green plant material (leaves, stems) contains	
15 – 30	kg N
15 – 30	kg K
2 – 4	kg P
1 t of roots (beets) or tubers contains	
1.5 – 3	kg N
4 – 5	kg K
0.3 – 0.6	kg P

Nutrient losses only occur from plant parts removed from the field. For example, if only grain is harvested and the straw remains on the field, only the plant nutrients present in the grain are lost from the system.

High nutrient losses may occur by *leaching*. The quantities lost depend much on climate, weather conditions, and soil properties. In Central Europe, with a rainfall of about 700 mm/a, ca. 25 – 50 % of the precipitation passes through the soil profile to a depth >1 m. Plant nutrients dissolved in this drainage water are lost from the soil. Table 10 shows maximum and minimum leaching rates obtained during a period of eight years by VÖMEL [69]. Generally, leaching rates are low if the soil clay content is high. High leaching rates prevail in fallow soils, low rates in soils with a permanent plant cover, e.g., grassland. Phosphate is effectively not leached. Leaching occurs mainly with the winter or monsoon rainfall. Under such humid conditions plant nutrients present in plant residues (stubble, straw, roots, leaves) also may be leached.

Table 10. Leaching rates of plant nutrients from soils [69]

Soil	Plant nutrient, kg ha^{-1} a^{-1}			
	N	K	Ca	Mg
Sand	12 – 52	7 – 17	110 – 300	17 – 34
Sandy loam	0 – 27	0 – 14	0 – 242	0 – 37
Loam	9 – 44	3 – 8	21 – 176	9 – 61
Clay	5 – 44	3 – 8	72 – 341	10 – 54

Volatile losses only play a role for nitrogen, which may be lost in form of NH_3, N_2, and N_2O (see Section Organic Matter of Soils and Nitrogen Turnover). Nutrient loss by conversion into a non-available form is only relevant for phosphate and in some cases for K^+.

2.5.2. *Alternative Plant Nutrition*

The terms “ecological agriculture” and “biological agriculture” are used as synonyms for “organic agriculture”. One of the main approaches of organic agriculture is a mixed farm system within a more or less closed nutrient cycle. With regard to plant nutrition the production system can be characterized by the following principles:

Nearly closed cycles of nutrients and organic matter within the farm
Predominant use of farmyard manure and compost
Slowly soluble P minerals, if necessary
K fertilizers not in the form of chloride

Besides nitrogen, which may be imported with manure, symbiotically bound nitrogen is the main N source. For this reason N_2 fixation by legumes is of great importance. Synthetic fertilizers are renounced. In the last few years major efforts were undertaken to quantify the cycles of nutrients as well as the organic matter cycles.

Organic agriculture has to deal with limited amounts of nutrients. Nutrient management, defined as systematic target-oriented organization of nutrient flow, is therefore considered as the optional combination of resources that are restricted or have to be released. Strategies must be adopted that make nutrients in the system internally available by achieving optimized utilization or which keep nutrients potentially available in the long term. The main nutrient flows in organic farm are fixed for the long term by organizing and optimizing the site-adapted crop rotation [70].

[Top of Page]

3. Standard Fertilizers

Heinrich Dittmar

Standard fertilizers include the products used in large quantities worldwide. They are applied to agricultural and large-scale garden crops. They can be classified as solid and liquid fertilizers.

3.1. Solid Fertilizers

Solid fertilizers are the most important group of fertilizers. Worldwide, nearly 90 % of all the nitrogen applied in fertilizers is in solid form (season or fertilizer year 1996/97). In Germany about 83.5 % of total nitrogen is applied in the solid form, and the corresponding figure in the United States is 44 %. Phosphate and potash are applied mainly in solid form. Solid fertilizers include granular, prilled, and compacted products (see Chap. Fertilizer Granulation).

A summary of the most important fertilizers can be found in [71].

3.1.1. *Straight Fertilizers*

Straight fertilizers contain only one nutrient, for instance, urea (N) or triple superphosphate (P_2O_5). Straight solid fertilizers are listed in Table 11.

Table 11. Straight fertilizers

Type	Production; main constituents	Analysis, wt %	Remarks	Ullmann keyword
Nitrogen fertilizers				
Calcium nitrate [13477-34-4]	synthetic	15.5 % N ($Ca(NO_3)_2$), NH_4 N, max. 1.5 %	fast acting; chiefly for special crops and refertilizing	→ Nitrates and Nitrites
Sodium nitrate [7631-99-4]	synthetic	16 % N ($NaNO_3$)	fast acting; chiefly for special crops and refertilizing	→ Nitrates and Nitrites
Chile saltpeter	from caliche; sodium nitrate	≥ 15 % N	fast acting; chiefly for special crops and refertilizing	
Ammonium nitrate [6484-52-2]	synthetic; may contain additives such as ground limestone, calcium sulfate, dolomite, magnesium sulfate, kieserite	34 % N(NH_4NO_3)	special storage provisions (see Chap. Storage, Transportation, and Application)	→ Ammonium Compounds – Ammonium Nitrate
Calcium ammonium nitrate (CAN)	synthetic; may contain additives such as ground limestone, calcium sulfate dolomite, magnesium sulfate, kieserite	26 – 28 % N, ≥ 2 % $CaCO_3$	versatile fertilizer, both fast and slow acting	→ Ammonium Compounds
Ammonium sulfate nitrate (ASN)	synthetic	added as limestone or dolomite 26 % N ($NH_4NO_3^+$ and $(NH_4)_2SO_4$), ≥ 5 % NO_3 N	versatile fertilizer with both fast and slow action	→ Ammonium Compounds
Magnesium ammonium nitrate	synthetic; ammonium nitrate and magnesium compounds (dolomite, magnesium carbonate, or magnesium sulfate)	20 % N (NH_4NO_3)	for soils and crops requiring magnesium	
Ammonium sulfate [7783-20-2]	synthetic, often as byproduct	≥ 6 % NO_3 N, 5 % MgO 21 % N ($(NH_4)_2SO_4$)	slow acting, for soils containing lime and/or high-precipitation areas	→ Ammonium Compounds – Ammonium Sulfate
Ammonium chloride [12125-02-9]	synthetic	≥ 25 % N (NH_4Cl)	rice fertilization, chiefly in Japan and India	→ Ammonium Compounds – Ammonium Chloride
Urea [57-13-6]	synthetic	46 % N ($CO(NH_2)_2$) biuret ≤ 1.2 %	optimal only when soil lime, heat, and moisture are appropriate; also suitable for foliar application; volatile losses are possible	→ Urea
Calcium cyanamide [156-62-7]	synthetic	20 – 22 % N; ≥ 75 % of total N from cyanamide; ca.40 % CaO 66 % N	slow acting, special requirements, also for weed control nitrification	→ Cyanamides – Calcium Cyanamide
Dicyandiamide [461-58-5]	synthetic		nitrification inhibitor, added pure to liquid manure; also as additive to straight and compound fertilizers containing ammonium	→ Cyanamides – Dicyandiamide
Phosphate fertilizers				
Basic slag (Thomas phosphate)	byproduct of steel production from ores containing phosphate; calcium silicophosphate	≥ 12 % P_2O_5 soluble in mineral acid, ≥ 75 % soluble in 2 % citric acid	phosphate containing up to 45 % CaO, versatile phosphate fertilizer	→ Phosphate Fertilizers
Superphosphate	digestion of ground phosphate rock with sulfuric acid; monocalcium phosphate with calcium sulfate	16 – 22 % P_2O_5 soluble in neutral ammonium citrate solution, 93 % water soluble	for all soils	→ Phosphate Fertilizers
Triple superphosphate	digestion of ground phosphate rock with phosphoric acid; monocalcium phosphate	45 % P_2O_5; soluble in neutral ammonium citrate solution, 93 % water soluble	for all soils	→ Phosphate Fertilizers
Partly digested phosphate rock	partial digestion of ground phosphate rock with sulfuric or phosphoric acid; monocalcium phosphate, tricalcium phosphate, calcium sulfate	≥ 20 % P_2O_5; soluble in mineral acid, 40 % water soluble	for all acidic soils (pH < 7)	→ Phosphate Fertilizers
Soft phosphate rock	grinding of soft phosphate rock; tricalcium phosphate and calcium carbonate	≥ 25 % P_2O_5 soluble in mineral acid, 55 % soluble in 2 % formic acid	for acidic soils and low-precipitation areas	→ Phosphate Fertilizers
Dicalcium phosphate [7789-77-7]	neutralization of phosphoric acid with calcium hydroxide dicalcium phosphate dihydrate	≥ 38 % P_2O_5 soluble in alkalized ammonium citrate; not water-soluble	for all soils	→ Phosphoric Acid and Phosphates
Thermal (fused)	thermal digestion of ground	≥ 25 % P_2O_5 soluble	for all soils and locations	

phosphate	phosphate rock with alkali-metal compounds and silicic acid; alkali-metal calcium phosphate and calcium silicate	in alkalized ammonium citrate solution and in citric acid		
Aluminum calcium phosphate	thermal digestion and grinding; amorphous aluminum and calcium phosphates	29 – 33 % P_2O_5 soluble in mineral acid, 75 % soluble in alkalized ammonium citrate solution	for all soils and locations	
Potassium fertilizers				
Potash ore	run-of-mine potash	≥ 10 % K_2O, ≥ 5 % MgO, contains sodium	for soils and crops where Na and Mg are important, especially cattle fodder	→ Potassium Compounds
Beneficiated potash ore	beneficiation of run-of-mine potash and mixing with potassium chloride	≥ 18 % K_2O	for all soils	→ Potassium Compounds
Potassium chloride [7447-40-7]	beneficiation of run-of-mine potash	≥ 37 % K_2O (up to 60 %)	for all crops not sensitive to chloride	→ Potassium Compounds
Potassium chloride with magnesium	beneficiation of run-of-mine potash and addition of Mg salts	≥ 37 % K_2O, ≥ 5 % MgO	on Mg-deficient soils for all crops not sensitive to chloride	→ Potassium Compounds
Potassium sulfate [7778-80-5]	synthetic	≥ 47 % K_2O, ≤ 3 % Cl	for all crops sensitive to chloride	→ Potassium Compounds
Potassium sulfate with magnesium	synthetic, from potassium sulfate, with addition of Mg salts; potassium sulfate and magnesium sulfate	≥ 22 % K_20, ≥ 8 % MgO; ≤ 3 % Cl	deficient soils for all crops sensitive to chloride	→ Potassium Compounds

3.1.2. *Multinutrient Fertilizers*

Multinutrient or compound fertilizers contain two or more nutrients. The term complex fertilizer refers to a compound fertilizer formed by mixing ingredients that react chemically. In bulk-blend or blended fertilizers (see Chap. Fertilizer Granulation), two or more granular fertilizers of similar size are mixed to form a compound fertilizer.

There are several routes for manufacturing fertilizers. An important route is the Odda process, in which phosphate rock is digested with nitric acid. Calcium nitrate is crystallized by cooling and removed, and the mother liquor is neutralized by addition of gaseous ammonia (see → Phosphate Fertilizers – Compound Fertilizers by the Nitro Route). Other important processes are based on digestion of phosphate rock with sulfuric acid and the so-called mixed-acid process [355]. For the production of NPK fertilizers, potassium compounds are added in the desired amount to the corresponding slurries. Magnesium (as kieserite or dolomite) and micronutrients may also be added.

NPK Fertilizers. According to the EEC Guidelines, NPK fertilizers must contain at least 3 % N plus 5 % P_2O_5 plus 5 % K_2O and at least 20 % total nutrients. The most commonly used grades (N-P_2O_5-K_2O, each in wt %) are

Nutrient ratio 1 : 1 : 1
15–15–15, 16–16–16, 17–17–17
Nutrient ratios 1 : 2 : 3 and 1 : 1.5 : 2
5–10–15, 6–12–18, 10–15–20
Nutrient ratio 1 : 1 : 1.5 – 1.7
13–13–21, 14–14–20, 12–12–17
Nutrient ratios 3 : 1 : 1 and 2 : 1 : 1
24–8-8, 20–10–10
Low-phosphate grades
15–5-20, 15–9-15

If additional numbers are given in a fertilizer grade, the fourth is the wt % MgO and the fifth is wt % S. Micronutrient contents may also be stated. In some countries the grade is expressed in terms of the elements rather than oxides.

The NPK fertilizers have the important advantage of simplified application, since all the important nutrients can be distributed in one operation. Each grain of fertilizer has the same content of nutrients. Serious errors are prevented by the harmonic nutrient ratio, provided the metering rate is correct. The nitrogen is usually present as nitrate and ammonium N in roughly equal parts. The phosphate is 30 – 90 % water-soluble, the rest being soluble in ammonium citrate solution. Most of the potassium is present as the chloride; the sulfate is used for chloride-sensitive crops.

In bulk-blended products (see Section Bulk Blending), the individual fertilizers are combined in the desired nutrient ratio. The operational advantage is the same as that of synthetic NPK fertilizers. Because, however, the individual granular products may differ in grain-size spectrum, granule surface characteristics, and density, segregation may occur during handling, storage, packaging and even during application. These products are therefore suitable for practical use only when the individual components have similar physical qualities.

NP Fertilizers. The minimum analysis for NP fertilizers under the EEC Guidelines is 3 % N and 5 % P_2O_5 and at least 18 % total nutrients. Common grades are 20–20, 22–22, 26–14, 11–52, 16–48, and 18–46. These products are appropriate for potassium-rich soils or where potash is supplied as a separate fertilizer.

NK Fertilizers. The minimum analysis for NK fertilizers under the EEC Guidelines is 3 % N and 5 % K_2O and at least 18 % total nutrients. These products are suitable for phosphate-rich soils or where phosphate is distributed separately.

PK Fertilizers. In the group of PK fertilizers, all combinations of the straight phosphate and potassium components listed in Table 11 are possible. In general, the materials are first milled and then mixed and granulated, so that a fairly homogeneous mixture is obtained. Some products are also made by bulk blending. The EEC Guidelines set forth a minimum analysis of 5 % P_2O_5, 5 % K_2O, and at least 18 % nutrients. Magnesium and micronutrient boron can be added.

3.1.3. *Lime Fertilizers*

Solid fertilizers also include lime fertilizers. The main purpose of using lime is to optimize soil pH; a secondary purpose is to supply calcium as a plant nutrient. The use of large amounts of lime to increase the pH is referred to as soil-improvement liming. Use to maintain the present pH is called maintenance liming.

The starting materials for lime fertilizers are limestone [1317-65-3] and dolomite [17069-72-6]. These are marketed in various forms. National fertilizer regulations (e.g., the type list in the Federal Republic of Germany's fertilizer law, see Chap. Legal Aspects) govern the fineness of grinding. Calcination at

900 – 1400 °C yields quicklime CaO; hydration with water gives slaked lime $Ca(OH)_2$. The most immediately effective form is finely divided quicklime with a particle size of ca. 0.15 mm or less. If a lime grade contains at least 15 % MgO or $MgCO_3$, it can be called magnesium lime. The content of MgO depends on the starting material (proportion of dolomite) and may be up to 40 %.

Calcium carbonates [471-34-1], $CaCO_3$, act slowly. They are recommended above all for lighter soils. Unslaked and slaked limes are faster acting. They are suitable mainly for loamy and clayey soils.

Besides these lime products from natural rock, there are also limes from industrial processes. They include smelting lime and converter lime, which are steel-industry byproducts. Converter lime with phosphate must contain 40 % CaO + MgO and also at least 5 % P_2O_5. These products must also satisfy minimum requirements on fineness to ensure sufficiently fast action.

Finally, the refining of beet sugar yields a product containing lime. According to the fertilizer law in the Federal Republic of Germany, this lime form must contain at least 30 % CaO and 5 % MgO.

3.1.4. *Magnesium Fertilizers*

The following magnesium fertilizers are offered in commerce: kieserite [14567-64-7] (27 % MgO) for soil application, and Epsom salts [7487-88-9] (17 % MgO) for foliar application in liquid form.

3.2. Liquid Fertilizers

Only solid fertilizers were produced and used up to ca. 1950: lower production costs, higher nutrient concentrations, and the ease of making compound fertilizers were for a long time the reasons that development was limited to the solid fertilizers. Since then, liquid fertilizers have also been developed and supplied to agriculture. Particularly in the United States, liquid fertilizers have come into heavy use. Modern production methods have lowered production costs, even for liquid fertilizers with high nutrient concentrations.

Homogeneous liquid fertilizers, in contrast to solid fertilizers, present no special problems during application by the farmer. Furthermore the storage of liquid fertilizers is less difficult than that of solid ones. Small amounts of herbicides and insecticides can be mixed with liquid fertilizers far more easily. Production plants for solid fertilizers are much more costly than those for liquid fertilizers. Liquid fertilizers have the drawbacks that they usually have lower nutrient content and are sensitive to impurities, as well as to precipitation and crystallization, especially caused by magnesium and fluorine.

Liquid fertilizers are classified as (1) anhydrous ammonia [7664-41-7] with 82 wt % N at high pressure, (2) aqueous ammonia with up to 24 wt % N, (3) ammoniates (ammoniated ammonium nitrate and/or urea solutions) with up to 50 wt % N at moderate to atmospheric pressure, and (4) nonpressure urea – ammonium nitrate solutions with up to 32 wt % N [72]. Compound liquid fertilizers include both clear liquids and suspensions.

The growing interest in liquid fertilizers results in large part from the fact that field spraying can be used for specific, exactly meterable, inexpensive, clean application with an injector. Even low nitrogen rates of 15 – 30 kg/ha can be exactly and uniformly metered out in liquid form.

Liquid-fertilizer plants are classified according to type of operation as hot mix or cold mix. Hot-mix plants use phosphoric acid and ammonia, whereby hot mix refers to the heat of reaction. Cold-mix plants mix ammonium phosphate solution with other ingredients; no heat of reaction is evolved. Cold-mix plants are popular in the United States, because they are simple and inexpensive. They are essentially a blending and mixing operation, the liquid counterpart of the bulk-blend plants (see Section Bulk Blending).

Table 12 lists the consumption of nitrogen in liquid fertilizers and their share of total nitrogen consumption by countries. In Germany consumption of nitrogen in liquids has risen since the season 1985/86, but total nitrogen consumption is decreasing [72]. The use of liquid ammonia plays no role in Germany and has strongly declined in Denmark. In the United States more nitrogen is consumed in liquid than in solid form.

Table 12. Consumption of liquid fertilizers and their share of total nitrogen consumption

Country and fertilizer year *	Liquid ammonia direct application		Nitrogen solutions		Total liquids		Total N

* The fertilizer year (season) runs from July 1 to 30 next year.
** Preliminary.

Liquid fertilizers can be easily mixed with a variety of micronutrients and agricultural pesticides. The dissolving of micronutrients in clear liquid fertilizers is promoted by gelatinizing agents or by complexing with polyphosphates. The pulverized additions such as copper sulfate, sodium molybdate, sodium borate, zinc oxide, or manganese oxide, which are mixed with suspensions [73], can be suspended in water by stirring.

Nonpressure liquid fertilizers are generally stored in concrete or mild steel tanks [308, p. 129]. A corrosion inhibitor is required in the case of nonpressure urea – ammonium nitrate solution. Concrete tanks have the shape of vertical cylinders. The tanks should be lined with a film of a durable plastic such as poly (vinyl chloride). Before lining, the concrete tank must be protectively coated [74]. For pressurized liquid fertilizers, double-walled vessels with leak warning systems should be employed. When single-walled tanks are used, a retaining basin must be erected.

3.2.1. *Nitrogen Liquids*

Liquid Ammonia. Since 1950, liquid ammonia has found increasing use as a direct-application fertilizer, especially in the United States, since it can be produced in large amounts at low cost. Because of its high vapor pressure (6 bar at 10 °C, 9 bar at 20 °C, and 12 bar at 30 °C), anhydrous ammonia must be stored and transported in pressure vessels and applied with special equipment.

Ammonia is injected into the soil to a depth of roughly 15 cm with injection prongs. In general, the equipment suitable for this purpose deposits the fertilizer in a pipe whose diameter depends on the soil type and soil moisture content. Figures 12 and 13 show the ammonia loss as a function of the soil type, the soil water content, and the depth of application [75]. If the soil contains 15 % water, the NH_3 loss is virtually independent of depth and, at about the 1 % level, can be neglected. Despite some advantages, the application of liquid ammonia is too expensive for most farmers in the EC. A publication for farmers on the safe use of liquid ammonia is available [76]. For storage and transportation, see ⟶ Ammonia and [308, p. 73]

Figure 12. Ammonia losses as a function of application depth for three types of air-dry soils

Figure 13. Ammonia loss as a function of soil water content for three depths of application

Pressurized Nitrogen Liquids. Together with ammonia, ammonium nitrate and/or urea can be converted into pressurized aqueous nitrogen fertilizers. The following categories are distinguished: low-pressure solutions (up to 1.3 bar) for direct application in agriculture, medium-pressure solutions (up to 7 bar), mostly used for ammoniating superphosphates or phosphoric acid, and high-pressure solutions (over 7 bar), used only for ammoniation. Table 13 lists some nitrogen solutions with their saturation temperatures and vapor pressures at 40 °C (313 K) [77].

Table 13. Nomenclature and physical properties of some nitrogen solutions

% N × 10	Composition *	Vapor pressure at 40 °C, bar **	Saturation temperature, °C
410	22–65–0	0.7	– 6
410	26–56–0	1.2	–32
444	25–55–10	1.5	–29

* HN_3–NH_4NO_3–$(NH_2)_2CO$, wt %.
** Multiply by 0.1 to convert to MPa.

Nonpressure Nitrogen Liquids. Nitrogen solutions that contain little or no ammonia have no significant vapor pressure at ambient temperatures. The most common nonpressure liquid nitrogen fertilizers comprise mixtures of ammonium nitrate, urea, and water (UAN), which are the most popular nitrogen fertilizers in the United States. A commercial solution might have the following composition:

Ammonium nitrate	39.5 % = 14 % N
Urea	30.5 % = 14 % N
Water	30.0 %
UAN	100.0 % = 28 % N

The density at 15 °C is ca. 1.28 g/cm^3, corresponding to 36 kg of nitrogen in 100 L of the product.

Figure 14 gives solubility isotherms and phase boundaries for the ammonium nitrate – urea – water system. In order to optimize the amount of UAN as a function of temperature during transportation and in the field, the UAN composition is adjusted to suit the conditions [77], [79]. This is especially important for winter application. Among almost-nonpressure nitrogen solutions, mixtures containing added NH_3 (see Table 14) should also be mentioned [80].

Table 14. Composition, nitrogen concentration (N), and crystallization temperature (T_c) of nitrogen solutions [80]

Composition, wt %				N,	T_c,	Pressure at 10 °C,
NH_3	NH_4NO_3	Urea	H_2O	wt %	°C	bar *
24	56	10	10	44	–26	0.3

Figure 14. The ammonium nitrate – urea – water system [77], [78]

Solid lines are solubility isotherms; dotted lines show phase boundaries; dashed lines show constant nitrogen content.

A urea – ammonium nitrate solution can be produced by dissolving solid urea in an ammonium nitrate solution. If the raw materials are solid urea and ammonium nitrate, UAN can be produced in a slightly modified dissolver. Figure 15 gives a simplified diagram of such a production unit.

Figure 15. Production of urea – ammonium nitrate solution [112]

a) Ratio controller; b) Mixer; c) Cooler; d) Storage tank

The desired ammonium nitrate : urea ratio is obtained by mixing a 75 – 80 % urea solution at 120 °C with an 80 – 85 % ammonium nitrate solution at 40 °C, the quantities being controlled. After the addition of water, the liquid fertilizer is transferred to a storage tank after passing via a cooler. The mixer and cooler are made of stainless steel, and the equipment downstream of the cooler are made of carbon steel [94]

Since urea – ammonium nitrate solutions attack ordinary steels, steel storage tanks and tank cars should be coated with Derakane-470, a poly(vinyl ester) [82], or lined with polypropylene or polyethylene [83]. This practice also prevents stress-corrosion cracking of the steels, especially in the presence of $(NH_4)_2CO_3$ [84]. Poly(vinylidene fluoride) provides excellent corrosion protection up to 120 – 130 °C [83]. The most common inhibitor for these solutions is anhydrous ammonia, which is used to adjust the pH to 7. Ammonium thiocyanate and ammonium phosphate are also effective [308, p. 129]

In the production and use of UAN, such solutions can explode if they are evaporated to <5 % water and simultaneously heated, especially when the two components have become segregated [85].

3.2.2. *Multinutrient Liquids*

Liquid mixed fertilizers consist of aqueous solutions and dispersions of the nutrients nitrogen, phosphate, and potash. These liquid mixed fertilizers are produced mainly from phosphoric acid, anhydrous ammonia or aqueous ammonia, ammonium nitrate, urea, and potassium salts, chiefly KCl but also K_2SO_4 (hot mix). In most cases, fine-grained potassium chloride, with a somewhat higher potash content (62 % K_2O) than the normal fertilizer salt, is employed because it dissolves better. If only solid raw materials are used, the N-P-K grade of the liquid mixed fertilizer can be varied only over a narrow range. The following solid nitrogenous components are mainly employed: ammonium nitrate, urea, monoammonium phosphate, and diammonium phosphate (cold mix).

For intensive field and greenhouse cultivation of vegetables, etc., the nutrients can be introduced into the watering system in the form of a low-percentage nutrient solution. Because this solution is often delivered directly to the roots through hoses, it should have the lowest possible level of impurities.

3.2.2.1. *NP Liquids*

In the early 1950s the commercial production of mixed liquid fertilizers was started in the United States. Pure electric-furnace orthophosphoric acid was used as the phosphate source. The acid was ammoniated to give an 8–24–0 grade liquid which does not salt out at – 8 °C. At mixing plants, this base solution was mixed with urea – ammonium nitrate solution to give a liquid containing ca. 28 – 32 % nitrogen. An additional potassium content was obtained by dissolving potassium chloride in the liquid. Maximum-mix grades attainable in this way included 13–13–0 and 7–7-7. A problem was the low concentrations of the 8–24–0 base solution and the final liquid mixes. Moreover, use of the cheaper wet-process orthophosphoric acid was not possible, because on ammoniation of such acids, iron, aluminum, magnesium and other impurities form voluminous, gelatinous, and crystalline precipitates that are difficult to handle.

In 1957 TVA introduced superphosphoric acid and base solutions made by ammoniation thereof [86]. The superphosphoric acid, initially produced by the electric-furnace process, contained ca. 76 % P_2O_5 as compared to 54 % P_2O_5 in commercial wet-process acid. At this higher P_2O_5 concentration, ca. 50 % of the P_2O_5 is in the form of pyrophosphoric, tripolyphosphoric, and tetrapolyphosphoric acids [88]. Because of higher solubility of the ammonium salts of these polyphosphoric acids, ammoniation of superphosphoric acid allowed production of higher grade base solution (10–34–0 instead of 8–24–0) and higher grade mixed fertilizer solutions. A further advantage was that the polyphosphates are effective sequestering agents that prevent precipitation of many metal ions. The kinetics of formation of ammonium polyphosphates are reported in [87].

Although the introduction of superphosphoric acid was an effective solution to the problem of low-grade liquids, there were still the high costs of the electric-furnace acid process. Studies were undertaken to produce usable superphosphoric acid by concentration of the cheaper (54 % P_2O_5) wet-process phosphoric acid to about 72 % P_2O_5 and a polyphosphate content of 45 – 50 %. Problems of the wet-process superphosphoric acid of this concentration were its high viscosity and the poor storage properties of the 10–34–0 base solution derived from it. Although the polyphosphate content of the liquid initially keeps impurities in solution in complexed form, precipitates may still form during storage if the acid used in ammoniation had too high an impurity level and the polyphosphate concentration is too low. A frequent problem with NP liquids is the precipitation of insoluble magnesium compounds. If 0.4 wt % magnesium (calculated as oxide) is present, the storage time before appearance of cloudy precipitates is only about one month. For magnesium oxide concentrations of 0.2 % and 0.1 %, the storage life is about 1 – 2 years [89].

The usual raw material for phosphoric acid productions, apatite, with its impurities and its variable composition, is not a simple raw material. In the production of phosphoric acid, however, most of the impurities (e.g., aluminum, iron, and magnesium compounds) remain behind in the acid slurry.

The removal of the impurities from the wet-process phosphoric acid (Fe, Al, Mg, Ca, SO_3, F) is necessary for storage and application of the liquid fertilizer. Two typical processes reduce the concentrations of the most troublesome impurities significantly (Table 15) [95]. Process B, which is used in Europe, reduces the impurity concentrations to lower levels than the U.S. Process A, while not reducing P_2O_5 concentration as much; however, Process B is more expensive.

Table 15. Purification of wet-process phosphoric acid

	Raw acid	Purified acid Process A	Purified acid Process B
P_2O_2	52.5	40.4	48.9
Fe	0.6	0.2	0.07
Al	0.9	0.3	0.01
Mg	0.3	0.03	0.001
Fe	0.8	0.3	0.06

The cleaning of the wet-process phosphoric acid by means of continuous extraction with ammonia and acetone has been described for the “green acid” from North Carolina phosphate rock and the “black acid” from Florida phosphate rock [90]. An extraction process is described in [91]. For the use of chelating agents, see [92, p. 58].

Addition of ammonium fluoride to aqueous aluminum phosphate-containing slurries precipitates aluminum as $(NH_4)_3AlF_6$ and forms ammonium and diammonium phosphate:

$$6\,NH_4F + AlPO_4 \rightarrow (NH_4)_3AlF_6 + (NH_4)_2HPO_4 + NH_3$$

resulting in a filtrate that can be subsequently worked up to give a liquid fertilizer.

Figure 16 shows how the polyphosphate content and the N : P_2O_5 ratio affect the solubility of ammonium phosphates at 0 °C. The bottom curve represents the solubility of the orthophosphates. The middle and top curves demonstrate the increase in solubility as the polyphosphate content increases [93].

Polyphosphate contents as percent of total P_2O_5: a) 0; b) 45; c) 70

Crystallizing phases: 1) $(NH_4)H_2PO_4$; 2) $(NH_4)_2HPO_4$; 3) $(NH_4)_3HP_2O_7 \cdot H_2O$; 4) $(NH_4)_5P_3O_{10} \cdot 2\,H_2O$; 5) $(NH_4)_2HPO_4 \cdot 2\,H_2O$; 6) $(NH_4)_4P_2O_7 \cdot H_2O$

Table 16 characterizes NP base solutions made from superphosphoric acid. The two solutions are 10 – 34 from wet-process superacid and 11 – 37 from furnace-grade superacid. The 10 – 34 NP solution is used predominantly [77].

Table 16. Composition of NP base solutions [77]

Grade	Phosphoric acid, wt % P_2O_5	Percentage composition * Ortho-phosphate	Pyro-phosphate	Tripoly-phosphate	Tetrapoly-phosphate	Higher phosphates
10–34–0	76	49	42	8	1	0
11–37–0	79 – 80	29	42	21	5	3
	80 – 81	20	37	23	10	10

* Distribution of P_2O_5 sources: of the total P_2O_5 present (34 or 37 wt %), the percentages given in the table are present in the form of orthophosphate, polyphosphate, etc.

A large number of experimental data points were subjected to regression analysis. With the resulting equation, the total nutrient concentration in NP solutions made from ammonium phosphates and urea at 0 – 50 °C can be calculated with a relative error of 1 % or else determined with a nomograph [80].

Figure 17 shows schematically a plant for producing NP base solutions (tank reactor process).

Figure 17. Plant for producing NP solution from superphosphoric acid [77]

a) Reactor; b, c, and d) Coolers; e) Storage tank

Superphosphoric acid, usually containing 40 to 50 % of the P_2O_5 as polyphosphates, ammonia, and water are continuously fed to a stirred-tank reactor. A heat exchanger operating in closed cycle holds the temperature in the reactor at roughly 70 °C. The solution concentration is controlled through density measurement, and the N : P_2O_5 ratio is controlled by means of the pH. The NP solution outlet from the reactor is cooled to 35 °C in another heat exchanger (c) before being transferred to a storage tank. To minimize hydrolysis of polyphosphate to orthophosphate, the product is further cooled to ca. 20 °C and the storage tank is protected from sunlight. The polyphosphate content of the product is always slightly lower than that of the feed acid. For example, a base solution containing about 50 % polyphosphate, which is about the minimum polyphosphate content of the product with acceptable storage properties, requires a feed acid containing 55 % polyphosphate.

Because of the expensive heat-exchange problems — heat must be supplied in the production of superphosphoric acid and removed in the subsequent ammoniation step — other techniques have been developed for producing ammonium polyphosphate solution from orthophosphoric acid in a *direct process*, thereby largely eliminating the expensive heat exchange. Two examples are the Swift process and the Tennessee Valley Authority (TVA) process.

In the Swift process (Swift Agricultural Chemical Corporation), ammonia gas reacts in a jet reactor (Fig. 18) with preheated wet-process phosphoric acid to produce ammonium polyphosphate. The phosphate melt inlet to the mixing tank is converted to liquid fertilizer by the addition of water; the grade produced is usually 10–34–0. The extent of polymerization depends on the temperature that prevails in the process reactor. At 300 °C, it is about 60 %. In addition to clear 10–34–0 liquid fertilizer, a 12–40–0 suspension can also be obtained with this process [94].

The TVA process uses a T reactor (Fig. 19) to produce ammonium polyphosphate. Wet-process phosphoric acid (52 – 54 wt % P_2O_5) is preheated and then

partly neutralized by ammonia in a simple spray washer (spray tower). The solution is then fed into the T reactor, which is also supplied with heated anhydrous ammonia from the other side. At the adjusted temperature of 232 – 243 °C, the reaction with ammonia goes to completion while the residual water is simultaneously vaporized and a foamy polyphosphate melt is formed [95]. After the product passes through a rotary separator (disengager), excess ammonia and steam are removed; the ammonia is scrubbed out, and the steam is discharged. From the melt, with a polyphosphate content of roughly 50 %, either clear liquid fertilizers such as 10–34–0 or suspensions such as 10–37–0 can be produced [95], [96].

The T reactor process has enabled reasonable equipment costs, process simplicity, and efficiency in the production of high-quality liquid fertilizers. The unique feature of the process is the conversion of a low-polyphosphate (20 – 35 %) superphosphoric acid to an high-polyphosphate (ca. 80 %) 10–34–0 or 11–37–0 base solution. The high polyphosphate content substantially improves the stability, storage life, and handling properties of the base solutions and NPK liquids. In contrast to the tank-reactor process the reaction is accomplished in a limited volume of the pipe reactor with minimal heat losses [97].

Figure 19. TVA process for producing NP solution from orthophosphoric acid [94]

a) Acid heater; b) Spray tower; c) T reactor; d) Rotating disengager; e) Ammonia preheater

In the Ugine Kuhlmann process [98], clear NP liquid fertilizers with good storage properties are produced from *unpurified wet-process phosphoric acid* [90].

The crude acid is first treated with urea to yield urea phosphate, which is crystallized and separated. The mineral impurities remaining in the mother liquor can be used in the production of solid fertilizers. Thus there is no waste disposal problem. In the second reaction step, the urea phosphate is reacted with ammonia, yielding a urea – ammonium polyphosphate melt, which is dissolved in water to obtain a 16–30–0 liquid fertilizer.

3.2.2.2. *NPK liquids*

Liquid NPK fertilizers are produced by adding a potassium component, usually potassium chloride, to UAN and NP solutions. The amount of water needed to dissolve 100 g of a mixture of UAN, NP solution, and potassium chloride at a specific temperature, as well as the solid phase, can be shown conveniently in the form of three-component phase diagrams [80]. Other triangular diagrams show the solubility relationships in mixed liquid fertilizer systems [97]. While the clear NP solutions with polyphosphate have compositions corresponding to those of solid fertilizers, the contents must be kept lower in clear ternary NPK solutions because potassium nitrate, which is formed from ammonium nitrate and potassium chloride, has a low solubility.

Table 17 presents several three-component liquid fertilizers obtained by mixing a 10–34–0 base solution with potassium chloride powder. The added component lowers the nutrient content from almost 39 % to ca. 29 – 30 % [99].

Table 17. Three-component liquid fertilizers produced by mixing 10–34–0 base solution with KCl [99]

Fertilizer type	Salt composition, wt %						Total nutrient analysis, wt % *	Freezing point, °C
	Ammonium orthophosphate	Ammonium polyphosphate	Urea	NH_4NO_3	KCl	H_2O		
1 : 1 : 1	7.93	10.11	7.8	16.3	15.6	42.2	28.85	–21
1 : 2 : 2	9.20	12.4	5.0	10.4	18.7	44.4	29.54	–18.5
1 : 1.5 : 1	10.70	13.65	7.3	15.3	14.1	38.4	30.57	–23.5
2 : 1 : 1	5.75	7.33	11.9	24.8	10.7	39.5	27.89	–24.5
1 : 1 : 0	16.10	20.5	15.9	33.2	0	14.3	38.60	–33

* $N + P_2O_5 + K_2O$.

Production takes place in either cold-mix or hot-mix plants [100], [312, p. 456]. Because cold-mix plants offer low investment costs and are easy to operate, they are in more widespread use. In a stirred vessel, the appropriate quantities of potassium chloride are added to the base solutions (e.g., 28–0-0 and 10–34–0) and mixed. Hot-mix plants, especially small-capacity ones, require relatively large investments and, because of their troublesome operation, must have well-trained personnel.

3.2.2.3. *UAS Liquids*

The use of high-analysis fertilizers containing little or no sulfur has led to soil sulfur deficiencies in areas far from industries. The critical level for sulfur in soil is 0.1 – 0.3 wt %. Sulfur deficiencies in the soil of Kuwait led to the development of a sulfur-containing liquid fertilizer: 21.2 wt % $(NH_4)_2SO_4$ + 37.6 wt % urea + 41.2 wt % water [101]. The total nitrogen content is 22 wt %, and the saturation temperature is 4 °C.

The reaction of urea with sulfuric acid

$$(NH_2)_2CO + H_2SO_4 \rightarrow (NH_2)_2CO \cdot H_2SO_4$$

yields liquid fertilizers with pH = 1. Because of corrosion, the plant must have polyethylene linings or else use expensive chrome – nickel – molybdenum steel. The following are typical UAS solutions [102]:

Sulfuric acid, wt %	N, wt %	S, wt %
28	9	27
17	16	49
15	17	52
10	18	55

Liquid fertilizers can be applied even in winter if ammonium thiosulfate is added in order to lower the salting-out temperature to – 18 °C. From the standpoint of nutrient content, this compound is better than water. Ammonium thiosulfate itself is a clear liquid fertilizer (12–0-0 + 26S) with a salting-out temperature of – 5 °

C [102].

3.2.3. *Suspensions*

Suspension fertilizers contain solid nutrient salts, especially potassium chloride, suspended in a concentrated ammonium phosphate solution. Their development has made it possible to attain nutrient contents corresponding to those of solid NPK fertilizers:

Solutions	Suspensions
8–8-8	15–15–15
3–9-9	7–21–21
2–16–12	5–15–30
10–5-5	20–10–10

What is more, suspension fertilizers have the advantage that low-priced phosphates that are difficult to dissolve in water can also be employed.

The storage and application of suspension fertilizers, however, is more difficult than that of clear liquid fertilizers, since the former tend to undergo sedimentation. If an easily handled suspension is desired, the product must be stirred vigorously before use. Swellable clays such as palygorskite (attapulgite), a magnesium silicate-containing clay (⟶ Clays), have proved suitable as suspending agents. Suspensions thus make special demands on technique. The methods of storage, transportation, and spraying cannot be transferred directly from clear liquid fertilizer solutions. As a rule, substantial changes in equipment are needed, and these require additional investments. The quality of spray distribution does not match that for clear fertilizer solutions either. For all these reasons, suspensions have scarcely become established in Europe, despite efforts to introduce them. In the United States, on the other hand, a larger scale of farming, together with a well-developed distribution service sector, has allowed the successful introduction of suspensions.

A suspension fertilizer can be produced from *solid monoammonium phosphate* by intensive stirring in water and simultaneous adding of ammonia. The addition of swellable clay (1 – 2 %) ensures a fairly stable suspension. By dilution, a product of grade 9–27–0 is obtained. Applied in a comparable way, it behaves much like the commercial 10–30–0 liquid fertilizer [103].

Anhydrous ammonia is used to improve the solubility and mixing of monoammonium phosphate. Ammonium orthophosphate displays the highest solubility at a molar ratio $NH_3 : H_3PO_4$ of 1.5. A turbine mixer is suitable for homogenizing the suspension obtained by the addition of KCl and 1 or 2 wt % palygorskite [104].

A stable suspension is obtained by ammoniating *wet-process orthophosphoric acid* (54 wt % P_2O_5) at 71 °C and a pH between 7.5 and 8.5. The product is then adjusted to the desired pH with a small amount of acid. Because of the fineness of the solid particles, the suspension (8–24–0) remains stable. After cooling, it can be blended with urea – ammonium nitrate solutions (32 % N) and potassium chloride to produce various compositions of liquid fertilizers [105].

A two-step process developed by TVA yields low-priced, high-analysis suspension fertilizers in which the phosphate component is obtained by ammoniating orthophosphoric acid (Fig. 20). In the first reaction step, the acid is partly ammoniated with ammonia, and the solution is held for about 30 min at 106 °C. In the second step, ammoniation is completed. Then the product is cooled to 60 °C, and the suspension of fine diammonium phosphate crystals is stabilized with 1.5 wt % clay. A fluid NPK fertilizer of 15–15–15 grade can be produced from the 12–40–0 suspension [106]. Raising the acid concentration from 54 wt % to 70 – 73 wt % P_2O_5 (wet-process superphosphoric acid) gives useful suspension fertilizers. In general, however, the Mg content is so high that prolonged storage is excluded because of the precipitation of struvite, $MgNH_4PO_4 \cdot 6\ H_2O$.

Figure 20. Production of orthophosphate suspensions

a) First reaction stage; b) Second reaction stage; c) Cooler; d) Slurry vessel for suspending agent; e) Product tank

This difficulty is avoided if *triple superphosphate* is employed as the sole phosphate source. Palygorskite is slurried with water in a mixing vessel, aqueous ammonia and urea – ammonium nitrate solution are added, and then finely-ground triple superphosphate and potassium chloride are incorporated. The suspensions made by this process have a typical grade of 12–12–12 [107]. The addition of palygorskite can be omitted if part of the triple superphosphate is first treated with aqueous ammonia to yield a voluminous precipitate, which then acts as a suspending agent for the other solid particles [108].

Suspensions from the Nitrophosphate Process. A low-cost process for producing a suspension fertilizer involves digesting crude phosphate with nitric acid. The slurry of phosphoric acid and calcium nitrate is inlet to a hot-mix plant and ammoniated to form an NP suspension fertilizer. Such processes have been developed in the United States, the USSR, and the Federal Republic of Germany [81], [109], [110]. Aside from the cheap raw material, the fixed costs of the fertilizer are relatively high. Since nitrophosphate processes yield suspension fertilizers with large amounts of calcium, the dilution effect of the calcium holds the nutrient content relatively low (e.g., 9–9-9 or 6–12–12).

High-Nitrogen Suspension Fertilizer. TVA has devised a promising method for producing a high-nitrogen suspension fertilizer (36 wt % N) [102]. This product is a mixture of microspray-crystallized urea and ammonium nitrate solution (76 wt % AN) with palygorskite. The composition is 57.5 wt % urea + 31.5 wt % ammonium nitrate + 10.0 wt % water + 1 wt % palygorskite [105], [108], [111].

Sulfur-Containing Suspensions. In regions where the effects of sulfur deficiency in the soil are pronounced in certain regions, sulfur in fertilizers not only increases yield but also can improve product quality. TVA has manufactured a 29–0–0–5S urea ammonium sulfate (UAS) suspension fertilizer in a pilot plant. The feedstocks are urea (70 % aqueous solution), sulfuric acid (93 %), anhydrous ammonia, and water. Clay (ca. 2 %) is added to the UAS solution to give the final product [102].

[Top of Page]

4. Special Fertilizers

Manfred Drach, Ralf Vosskamp, Martin E. Trenkel, Reinhold Gutser, Günter Steffens

The special fertilizers include water-soluble nutrient salts, foliar fertilizers, micronutrient fertilizers, slow- and controlled-release fertilizers, nitrification inhibitors, and organic fertilizers, including sewage sludge, compost and manure.

4.1. Water-Soluble Nutrient Salts

Especially for fertilization in commercial horticulture, but also for specialty field crops, water-soluble nutrient salts (e.g., ammonium nitrate, potassium nitrate, ammonium phosphate, magnesium sulfate) are preferably used with water-saving irrigation systems (drip irrigation/fertigation) and with soilless cultivation systems. Various crop-specific fertilizer recipes can be formulated with these salts. A convenient form for the consumer are multinutrient fertilizers made by mixing various water-soluble salts, which generally also include micronutrients. Such salt mixtures are available worldwide from most major fertilizer manufacturers.

From these salts and salt mixtures, the grower prepares highly concentrated master solutions, which for application are further diluted to render them plant-compatible and then fed into the irrigation system. By using appropriate automatic fertilizer systems it can be assured that irrigation intervals and concentration of the nutrient solution are adjusted to the crop's needs.

A distiction is made between urea-containing and urea-free nutrient salt mixtures. Since the application rate of nutrient salts is frequently monitored by means of conductivity, products containing urea cause problems as urea has no ionic conductivity and is therefore not detected. Therefore, products containing urea are mainly used for foliar fertilization (see Section Foliar Fertilizers) where these calibration problems do not exist and because urea nitrogen is the N form with the best uptake rate via the leaves.

A prerequisite for all nutrient salts is rapid dissolution in water without any residues. This is achieved by producing the salt mixtures from appropriate ingredients and by properly grinding them. Moreover, for special fields of application in horticulture (flood irrigation and soilless cultivation systems) they are rated by their nitrogen forms. For these fields of application, nitrate-based nutrient salts are preferred.

In principle, if appropriately diluted, all nutrient salts are suitable both for soil fertilization and for foliar fertilization.

4.2. Foliar Fertilizers

For over 100 years it has been known that nutrients can be taken up through the leaves. However, with some exceptions, plants cannot be provided with nutrients through the leaves alone, since even leafy plants such as potatoes cannot absorb sufficient nutrients through the leaves. Foliar fertilization, therefore, is usually a supplement to soil fertilization. However, it is often the case that proper foliar fertilization puts the plants in the position to utilize soil-derived nutrients better. Recent decades have seen foliar fertilizers come into use not only for special crops or in certain localities, but throughout agriculture.

Foliar fertilizers are substances that contain primary nutrients and/or micronutrients, are applied to the leaves, and are absorbed into the leaves. The most important foliar fertilizer is urea (46 % N) which is highly soluble in water and rapidly absorbed by plants via the leaves. Therefore, urea is frequently used as a component of fertilizer suspensions and solutions. In addition to nitrogen, other macro- and micronutrients can be added, frequently in a nutrient ratio tailored to the demand of specific target crops. Special raw materials and formulations ensure a good plant compatibility and optimum foliar nutrient uptake. Also used for foliar fertilization are solutions with organic ingredients (e.g., amino acids), readily soluble salts (e.g., potassium nitrate or micronutrients, mostly based on sulfate) and salt mixtures containing macronutrients and special micronutrient mixtures.

4.2.1. *Production*

Solid foliar fertilizers are produced by mixing salts that are readily soluble in water. Before application, the salts are dissolved for spraying. Liquid foliar fertilizers, which are made from readily soluble salts or solutions and adjusted to a given analysis, are also on the market. The production of suspensions for foliar application involves the use of dispersing agents, and in some cases ionic surfactants, to stabilize the spray.

4.2.2. *Application*

In order to achieve optimal utilization of nutrient uptake through the leaves, the nutrient salts must remain as long as possible in the dissolved liquid state on the leaf surface. For this reason, spraying in overcast weather or toward evening (“evening dew”) gives better results than spraying on dry days in bright sunlight. Depending on the sensitivity of the leaves and the concentration of the spray liquid, application in hot, sunny weather may cause burning. Table 18 gives the time required for 50 % absorption of nutrients applied to the leaves of bean plants [113].

Table 18. Nutrient absorption rates [113]

Nutrient	Time for 50 % uptake
Nitrogen	1 – 6 h
Phosphate	2.5 – 6 days
Potash	1 – 4 days
Calcium	1 – 4 days
Sulfur	5 – 10 days
Magnesium	1 h (20 % uptake)
Iron	24 h (8 % uptake)
Manganese	1 – 2 days
Zinc	1 day
Molybdenum	10 – 20 days

Nutrients placed on the leaf surface follow three paths to the leaf cells [114-116]. After the cuticle has been wet by the nutrient spray, the cutin swells, which increases the distances between the wax plates in the cuticle. As a result, the nutrients are able to diffuse through the cuticle and into the cell wall (Fig. 21). The nutrients can then diffuse into the space around the epidermal cell and to the cell membranes, where they can be absorbed, or they can diffuse further along the cell wall of the epidermal cell and adjoining cells, deeper into the leaf, where they can be absorbed by a parenchymal cell. Nutrients that have been absorbed by an epidermal cell can be transferred to other cells by cytoplasmic strands connecting the cells, the plasmodesmata, a second path. If surfactants are included in the nutrient spray, a third path becomes available: the nutrients can pass through the stomata into the air spaces of the leaf.

Figure 21. Access and transport paths for nutrients in leaves

Reasons for Using Foliar Fertilizers. Foliar fertilizers are applied to remedy obvious nutrient deficiencies. If a deficiency is recognized, the missing nutrient is supplied by spraying. If the deficiency is not well defined, complete foliar fertilizers or a mixed micronutrient fertilizer can be employed.

Another reason for foliar application is to remedy hidden (latent) nutrient deficiencies, which can seriously impair crop yield and quality.

Foliar fertilizers are also used to protect yield and quality, to meet peak nutrient demands (i.e., remedy latent deficiencies and stimulate the plants to absorb more nutrients from the soil), and to improve quality. The last point is especially important for special crops (wine, fruits, vegetables).

Advantages and Drawbacks of Foliar Fertilizers. Foliar application has a number of advantages over soil application: Nutrients act rapidly, nutrient utilization is high, nutrients are placed where they are needed, the risk of leaching losses and groundwater contamination is reduced. micronutrients are supplied to meet much of the demand for them, micronutrients are not fixed in the soil, application does not entail extra costs if fertilizers are combined with agricultural pesticides, and some nutritional problems can be cleared up only through application to the leaves or fruit (bitter pit in apples, stem necrosis in grapes).

The main disadvantages of foliar fertilization are that the action time is often short, the quantity of primary nutrients delivered is relatively small, and there are questions of compatibility in relation to concentration and prevailing weather conditions.

4.2.3. *Combination with Agricultural Pesticides*

Foliar fertilizers are usually applied along with agricultural pesticides for the following reasons [117]: to lower the cost of application, since pesticide spraying is required anyway; to reduce the stress due to the application of pesticide (e.g., certain herbicides); to improve the quality of pesticide spray liquids (lower the pH or increase the electrolyte content) and thus stabilize them; to reduce evaporation at low air humidity, so that most of the fine droplets reach the plant in liquid form; and to lower the surface tension of the water.

4.3. Micronutrients

The most important micronutrients (trace elements) are iron, manganese, boron, zinc, copper, and molybdenum. The delivery of micronutrients to plants is just as indispensable today as that of macronutrients or primary nutrients. Diseases resulting from an undersupply of micronutrients are seen more and more often as agriculture and gardening become more intensive, with a corresponding increase in plant nutrition [118]. For this reason, better and more specific micronutrient fertilizers have now been developed.

The term micronutrient also signifies that these substances are needed only in small quantities, often just 1 – 100 g per hectare and year. These small amounts are, however, absolutely necessary. But if the optimal dose is much exceeded, serious crop damage and loss of yield may occur. For boron, in particular, the difference between an adequate and an excessive amount is slight.

To work in the proper way, the micronutrients must be absorbed by the plants. Uptake is mainly in the form of ions: cations or metal – chelate ions of iron, manganese, copper, and zinc and anions in the case of boron and molybdenum (borates, molybdates). Absorption is through the leaves (foliar fertilizer) or the roots (soil solution).

4.3.1. *Micronutrient Forms*

Micronutrients are used in the following inorganic forms:

1. Various metal salts (sulfates, chlorides, nitrates)
2. Milled oxides
3. Metal flours and metal slags

Table 19 lists only those micronutrient compounds that are in common use. The table also states the nutrient analyses, the solubilities in water, and the various types of fertilizers in which the compounds appear.

Table 19. Micronutrient fertilizers

Substances and products	Formula	Analysis, wt %	Solubility, g/100 g H_2O	Uses
Salts (*technical*)				
Iron(II) sulfate heptahydrate	$FeSO_4 \cdot 7H_2O$	19.5	62.3	liquid fertilizers,
Manganese(II) sulfate monohydrate	$MnSO_4 \cdot H_2O$	32	63.0	nutrient-salt
Copper(II) sulfate pentahydrate	$CuSO_4 \cdot 5H_2O$	25	36.0	mixtures, solid
Zinc(II) sulfate monohydrate	$ZnSO_4 \cdot H_2O$	35.5	63.7	straight and
Zinc(II) sulfate heptahydrate	$ZnSO_4 \cdot 7H_2O$	22	165.5	multinutrient
Boric acid	H_3BO_3	17		fertilizers,
Colemanite (boron mineral)	$Ca_2B_6O_{11} \cdot 5H_2O$	11		micronutrient and
Disodium octaborate tetrahydrate *	$Na_2B_8O_{13} \cdot 4H_2O$	20.8	9.5	multimicronutrient
Hexammonium heptamolybdate tetrahydrate	$(NH_4)_6Mo_7O_{24} \cdot 4H_2O$	54		fertilizers
Oxides				
Manganese dioxide (mineral)	MnO_2	45		solid straight and
Zinc oxide (residual zinc)	ZnO	69		multinutirent
Molybdenum trioxide	MoO_3	60		fertilizers
Slags				
Copper slag flour		2.5 Cu, 0.05 Co		micronutrient fertilizers
Metal flours				
Manganese flour		20 Mn, 10 Fe, 0.5 Zn, 0.25 Cu		micronutrient
Copper flour		2.6 – 25 Cu		fertilizers

* Disodium octaborate is not a homogeneous substance. It has a $Na_2O : B_2O_3$ ratio of 1 : 4 and can be produced as a concentrated solution. It is sold by US Borax under the trade name Solubor.

In addition to these, the nitrates and chlorides of iron, manganese, copper, and zinc are also used, especially in concentrated liquid fertilizers. The trace-element nitrates and chlorides have high solubilities (e.g., 268 g per 100 g H_2O for $Fe(NO_3)_2 \cdot 6\,H_2O$ or 400 g per 100 g H_2O for $FeCl_3 \cdot 6\,H_2O$; some of the nitrates and chlorides of manganese, copper, and zinc have still higher values). Because of the price and the handling qualities in the solid state, however, the sulfates are preferred. Many crops are sensitive to trace-element chlorides in large amounts. At the levels usual in foliar application, however, this is certainly not a major problem. Trace-element sulfates and nitrates provide two nutrient elements each.

Because soluble iron compounds are fixed as phosphates or oxides in calcareous soils, organic complexes were first developed for this element. One successful complexing agent is ethylenediamine di(*o*-hydroxyphenylacetic acid) (EDDHA):

Other compounds of trace metals with *N*-carboxylalkylamino acids are less effective in the soil, especially with soil pH values > 7, but if applied on the leaves are superior to the EDDHA compounds and to the simple salt solutions.

The *N*-carboxylalkylamino acids have also come into wide use today as chelating agents for manganese, copper, and zinc:

EDTA. ethylenediaminetetraacetic acid
HEDTA. hydroxyethylethylenediaminetriacetic acid
DTPA. diethylenetriaminepentaacetic acid
EDDHA. ethylenediamine di(o-hydroxyphenylacetic acid)
EDDHMA. ethylenediamine di(*o*-hydroxy-*p*-methylphenylacetic acid)

For the formulas of the *N*-carboxylalkylamino acids, see ⟶ Ethylenediaminetetraacetic Acid and Related Chelating Agents, and the stability constants, see ⟶ Ethylenediaminetetraacetic Acid and Related Chelating Agents

Other chelating agents such as lignosulfonates and citric acid have so far been used only to a lesser extent.

4.3.2. *Production*

The list of fertilizers containing micronutrients comprises straight micronutrient fertilizers, combination micronutrient fertilizers, and ordinary fertilizers with micronutrients. All these types can be manufactured in either liquid or solid form. Among the solid micronutrient fertilizers, the powdered and fine-crystalline ones predominate, since nearly all of them can be dissolved in water and applied through the leaves. They generally consist of the several substances in Table 1 as well as the *N*-carboxyalkylamino acid chelates cited.

Solid micronutrient fertilizers for soil application include metal flours, metal slags, and micronutrient frits. Metal flours come from fabrication waste in the manganese production and processing industry and from specially prepared alloys. The source material is ground and granulated to between 0.25 and 1.5 mm. Metal slags such as copper slag flour are also won from waste products. The metal slags are quenched in water and comminuted to fine, powdery products.

Frits are made by melting glasses and incorporating the desired micronutrients (single-element and multi-element frits). The glasses are then finely milled [119].

Solid straight micronutrient fertilizers and multi-micronutrient fertilizers with complexing can be produced in various ways. One technique is to grind a metal sulfate with chelating agents, or several metal sulfates with chelating agents (in many cases borates, molybdates, and magnesium sulfate are added) and blending [120]. Chelation takes place when the material is dissolved in water before use. A second approach is to stir and thereby dissolve chelating acids and metal oxides (including magnesium oxide) in water at elevated temperatures; additives that cannot be chelated, such as borates and molybdates, are added; the product is further stirred, filtered, and spray-dried [121] or crystallized.

Liquid micronutrient fertilizers and combination micronutrient fertilizers can be prepared by the same technique but without the spray-drying step.

In the production of fertilizers with micronutrients, the micronutrients are usually added before granulation; in the case of liquid fertilizers, micronutrient compounds or chelates are dissolved along with the primary nutrient forms.

4.3.3. *Commercial Fertilizers*

Several firms in Western Europe manufacture pure micronutrients or combination micronutrient fertilizers, most of them in chelate form. Table 20 lists selected firms and examples of their products.

Table 20. Commercial fertilizers

Company	Products
ABM Chemical	Nevanaid Fe, finely powdered solid product with 9 % Fe (HEDTA)
(United Kingdom)	Nevanaid Fe, finely powdered solid product with 7 % Fe (DTPA)
	Nevanaid Mn, finely powdered solid product with 10 % Mn (EDTA)
Allied Colloids	Librel Fe-Dp, finely powdered solid product with 7 % Fe (DTPA)
(United Kingdom)	Librel Mn, finely powdered solid product with 13 % Mn (EDTA)
BASF	Fetrilon 13 %, spray-dried solid fertilizer with 13 % Fe (EDTA)
(Germany)	Fetrilon-Combi, spray-dried solid multimicronutrient fertilizer with 9 % MgO, 4 % Fe, 4 % Mn, 1.5 % Cu, 1.5 % Zn, 0.5 % B, 0.1 % Mo (all heavy metals as EDTA, boron as borate, Mo as molybdate)
	Nutribor, crystalline powder with 8 % B, 1 % Mn, 0.1 % Zn, 0.04 % Mo, 6 % N, 5 % MgO, 12 % S (EDTA)
	Solubor DF, microgranular with 17.5 % B
Ciba Geigy	Sequestrene 138, solid fertilizer with 6 % Fe (EDDHA), soil application
(Switzerland)	Ferrogan 330, solid fertilizer with 10 % Fe (DTPA)
Grace Rexoline	Rexene 224 Fe, powdered or granular fertilizer with 6 – 7 % Fe (EDDHMA), soil application
(Sweden)	Rexenol Cu, powdered solid fertilizer with 9 % Cu (HEDTA)
	Rexene Zn, liquid fertilizer with 6.5 % Zn (EDTA)

Urania (Germany) uses metal slags as raw material to produce granular copper fertilizers containing 2.5 % and 5 % Cu, as well as a copper – kieserite granular fertilizer with 2.5 % Cu and 21 % MgO. Similar micronutrient products and the same chelating agents are made in the United States and marketed as commercial fertilizers [119, pp. B68 to B83].

There are also fertilizers with micronutrient supplements, namely: granulated straight and multinutrient fertilizers, water-soluble nutrient salts, suspensions and solutions with micronutrients, which are chosen and added according to crop demand.

4.3.4. *Use*

In order to combat micronutrient deficiencies, either fertilization far exceeding actual depletion or directed foliar fertilization must be carried out [117, p. 128]. The annual depletion of micronutrients can be partly offset by the use of macronutrient fertilizers with micronutrients. On the basis of average micronutrient contents and average crops (rotation 70 % cereals, 20 % root crops, 10 % fodder), the following are withdrawn from the topsoil per hectare and year in central Europe [117, p. 122]: 400 – 700 g manganese, 260 – 400 g zinc, 150 – 200 g boron, 80 – 120 g copper. The amounts for grassland (per hectare and year) are 800 g manganese, 300 g zinc, 80 g copper, 50 g boron, and 0.5 g cobalt. In addition, leaching removes an average of 250 g manganese, 250 g boron, 100 g zinc, and 30 g copper per hectare and year [117, p. 122].

Normally, fertilization must more than make up for this consumption. Per hectare, boron-deficient soils must receive 1 – 2 kg of boron, and manganese-deficient soils must receive as much as 12 – 24 kg of manganese.

In order to prevent the development of latent deficiencies, micronutrients are often used in small quantities, especially for foliar application. This applies in particular to intensive cereal farming, where — even on well-supplied soils — the freely available micronutrients are soon consumed or else the nutrient flux at peak demand times cannot be covered from soil reserves. If relatively small amounts of a multi-micronutrient fertilizer are used in specific treatments during tillering and in the shoot and ear phases, latent deficiencies are generally eliminated and the yield potential is fully utilized [122], [123].

4.4. Slow- and Controlled-Release Fertilizers

4.4.1. *Introduction*

In plant nutrition, soil and plants are two antagonistic systems that compete for the nutrients available in or applied to the soil. This competition is the main reason why only a portion of nutrients is taken up and used by the plants and crops grown, while another portion is (temporarily) immobilized in the soil or lost by denitrification/volatilization and leaching (particularly of nitrogen) [124, p. 124]. The fertilizer industry has developed special types of fertilizers and fertilizer

modifications which avoid or at least reduce such losses, such as:

- Foliar fertilizers
- Slow and controlled-release fertilizers
- Nitrification and urease inhibitors; stabilized fertilizers

The utilization rate of nutrients is improved considerably by leaf application. However, in practice it is impossible to supply all the necessary nutrients via plant leaves [124, pp. 125 – 127], [125, pp. 14 – 16]. A more practical route is the use of nitrogen fertilizers which release the nutrients according to the plants' requirements, that is, slow- and controlled-release fertilizers.

Terminology. The Association of American Plant Food Control Officials (AAPFCO) gives the following definition: “Delay of initial availability or extended time of continued availability may occur by a variety of mechanisms. These include controlled water solubility of the material (by semipermeable coatings, occlusion, or by inherent water insolubility of polymers, natural nitrogenous organics, protein materials, or other chemical forms), by slow hydrolysis of water-soluble low molecular weight compounds, or by other unknown means” [126].

There is no official differentiation between slow-release and controlled-release fertilizers. However, the microbially degradable N products, such as urea – formaldehydes (UFs and other urea – aldehyde compositions), are commonly referred to in the trade as slow-release fertilizers, and coated or encapsulated products as controlled-release fertilizers [127, p. 12].

Advantages and Disadvantages. Slow- and controlled-release fertilizers reduce toxicity, especially in use with seedlings. The toxicity of conventional soluble fertilizers is caused by the high ionic concentrations resulting from quick dissolution. Consequently, these slow and controlled-release fertilizers permit the application of substantially larger fertilizer dressings (depot fertilization). This results in significant savings in labor, time, and energy. They also allow the full nutrient requirements of crops grown under plastic cover to be met (protected crop cultivation). These fertilizers significantly reduce possible losses of nutrients due to the gradual nutrient release (particularly losses of nitrate nitrogen). They also reduce evaporative losses of ammonia. They further contribute to a reduction in environmentally relevant gas emissions (N_2O) [127, pp. 15 – 16].

There are no standardized methods for reliable determination of the nutrient release pattern available as yet due to the lack of correlation between laboratory tests and field conditions. With urea – formaldehyde fertilizers, a proportion of the nitrogen content may be released extremely slowly or not at all. With sulfur-coated controlled-release fertilizers the initial nutrient release may be too rapid and cause damage to turf or the crop. Repeated use of sulfur-coated urea may also increase the acidity of the soil. Polymer-coated or encapsulated controlled-release fertilizers can cause an environmental problem since undesirable residues of the coating material may accumulate in the fields. However, the main disadvantage is that the cost of manufacturing slow- and controlled-release fertilizers is still considerably higher than that of conventional mineral fertilizers. At present their cost/benefit ratio prevents their wider use in general agriculture. Consequently, the vast majority is applied in nonagricultural sectors such as nurseries and greenhouses, golf courses, professional lawn care, as well as by consumers (home and garden) and landscape gardeners [127, pp. 17 – 18]. Total world consumption of slow- and controlled-release fertilizers is estimated at 562 000 t (1995/96), amounting to only 0.15 % of world total consumption of N + P_2O_5 + K_2O in the form of fertilizer material (ca. 380 × 10^6 t) [128].

Types of Slow- and Controlled-Release Fertilizers. The two most important groups are:

1. Condensation products of urea such as urea – formaldehydes (slow-release)
2. Coated or encapsulated fertilizers (controlled-release)

Of lesser importance are other organic chemicals, ion-exchange materials, and supergranules.

4.4.2. *Urea – Aldehyde Slow-Release Fertilizers*

Three types of urea – aldehyde condensation products (see also ⟶ Urea – Reaction of Urea and Its Derivatives with Aldehydes) have gained practical importance:

1. Urea – formaldehyde (UF)
2. Urea – isobutyraldehyde (IBDU/Isodur)
3. Urea – acetaldehyde/crotonaldehyde (CDU/Crotodur)

At pH values below 2, crotonaldehyde and acetaldehyde can form cyclic condensation products [131]. For production of urea – aldehyde condensates, see [129, pp. 3 – 87], [130, pp. 1 – 137], [132, pp. 153 – 156], [133], [134, pp. 247 – 279].

The urea – formaldehyde products have the largest share of the slow- and controlled-release fertilizer market (40 % of world consumption in 1995/96); IBDU- and CDU-based products are less widely used (15 % in 1995/96), since their manufacturing costs are even higher than that of urea – formaldehydes [127, pp. 61 – 63].

4.4.2.1. *Urea – Formaldehyde Condensation Products.*

Ureaform, as defined by the American Association of Plant Food Control Officials (AAPFCO) is the oldest type of urea – formaldehyde condensate. As early as 1924, Badische Anilin- & Soda-Fabrik (now BASF) registered the first patent (DRP 431 585) on urea – formaldehyde condensation fertilizers [135]. In the United States they were patented for use as fertilizers in 1947; commercial production began in 1955.

Ureaforms are a mixture of methylene – urea oligomers of various molecular masses, polymer chain lengths, and hence varying water solubilities, such as methylene diurea (MDU), and dimethylene triurea (DMTU). They also contain a certain amount of unchanged urea.

Manufacture. The manufacture of urea – formaldehyde products is a two step process [136, p.13], [137], [138], [139], [140], [141], [142], [143]:

$$NH_2CONH_2 + CH_2O \rightleftharpoons HOCH_2NHCONH_2$$

$$CH_2O + HOCH_2NHCONH_2 \rightleftharpoons HOCH_2NHCONHCH_2HO$$

First, urea and formaldehyde are combined to give the intermediates monomethylol- [1000-82-4] and dimethylolurea [140-95-4]. Under acidic conditions these methylolureas react with further urea to give various oligomers of methylene urea:

$$NH_2CONH_2 + HOCH_2NHCONH_2 \rightarrow NH_2CONHCH_2NHCONH_2 + H_2O$$

In the production of granular urea – formaldehyde products, water must be removed by evaporation. The main problem in the manufacture of urea – formaldehyde slow-release fertilizers is the production of condensation oligomers in the desired proportions. A number of processes can be used to meet this target (e.g., dilute- and concentrated-solution processes). The procedure commonly applied is to use suspensions of methylene urea or solutions of urea and methylol urea as well as solid product. In this way the condensation reactions take place in the granulator itself (in situ process) [144].

Properties. The urea – formaldehyde products are separated into the following three fractions:

1. Fraction I: cold water (25 °C) soluble (CWS), containing residual urea, methylene diurea (MDU), dimethylene triureas (DMTU), and other soluble reaction products. Depending on soil temperature the availability of Fraction I nitrogen is slow.
2. Fraction II: hot water (100 °C) soluble (HWS), containing methylene ureas of intermediate chain length: slow-acting nitrogen.
3. Fraction III: hot water insoluble (HWI) containing methylene ureas of very long chain length, insoluble in both cold and hot water; extremely slow-acting or ineffective in plant nutrition.

How the proportion of the different methylene ureas affects the release of nitrogen and the nitrogen efficiency are expressed by the activity index (AI). The AI is calculated from the solubility fractions of the fertilizer under various conditions [127, p. 22]. In the past urea – formaldehydes had an AI of about 40 – 50; more recent formulations have AI values of 55 – 65.

In general, the nitrogen content of urea – formaldehyde condensation products ranges from 35 to 42 % N. The American Association of Plant Food Control Officials (AAPFCO) specifies a minimum AI of 40, with at least 60 % of the nitrogen as cold water insoluble nitrogen (CWI N), a total N content of at least 35 % N, and an unreacted urea nitrogen content of less than 15 % of total nitrogen. In the United States, Western Europe, the Former Soviet Union, and Israel research has been carried out to reduce the fraction of HWI nitrogen [148]. In the 1980s research resulted in the development of MDU/DMTU compositions which consist of shorter chain polymers with at least 60 % CWS polymer nitrogen. Although they have higher contents of CWS nitrogen, they still have safer agronomic and environmental properties than conventional nitrogen fertilizers. Commercial products are white, colorless powders or granules. In wet granulation, the pH value and temperature must be controlled to avoid hydrolysis and thus losses of formaldehyde. Under normal conditions the finished products are stable in handling and storage. Typical properties of urea – formaldehyde products are given in Table 21.

Table 21. Properties of typical ureaforms

Property	Nitroform*	Azolon**
Total N, wt %	37.4	38.0
Insoluble in cold water, wt %	26.9	26.0
Soluble in hot water, wt %	15.4	10.4
Activity index	43	60
Bulk density, t/m^3		0.75
Granule size, mm	0.5 – 2.0	1.0 – 4

* Trademark of Nor-AM; BASF product analysis 1980.
** Trademark of Aglukon; analysis from [149].

Application. The release of plant-available nitrogen from urea – formaldehyde products mainly involves decomposition through microbial activity and dissolution by hydrolysis. Consequently, factors affecting microbial activity, such as higher temperature, moisture, pH value and oxygen availability, also affect the release of nitrogen. These products are therefore widely used in warmer climates (in the Mediterranean region of Europe and in the southern and southwestern United States).

4.4.2.2. *Other Urea – Aldehyde Condensation Products*

Due to the higher costs involved in the combination of urea with higher aldehydes, only two products have gained commercial importance. These are IBDU or Isodur (urea + isobutyraldehyde) and CDU or Crotodur (urea + acetaldehyde or crotonaldehyde).

IBDU (Isodur). Products derived through the combination of urea and isobutyraldehyde consist of mainly isobutylidene diurea [6104-30-9] (with small quantities of slow-acting by-products).

Isobutylidene diurea

Manufacture. Isobutylidene diurea is manufactured by condensation of liquid isobutyraldehyde with urea (either in solution or solid form). In contrast to urea – formaldehyde, the reaction of urea with isobutyraldehyde results in a single oligomer. To obtain an optimal proportion of IBDU it is important to stop the reaction by neutralization when the IBDU yield is at a maximum.

Isobutylidene diurea is produced in Japan and Germany [130], [150], [151], [152] (Mitsubishi, BASF). In the BASF process urea reacts with isobutyraldehyde in an aqueous solution to give a high proportion of slow-release N [153]. A Mitsubishi-developed process is operated by IB Chemicals in Alabama.

Properties and Application. IBDU is a white crystalline solid with a theoretical N content of 32.18 wt % N. The official definition (AAPFCO) requires 30 wt % N, of which 90 % must be cold water insoluble prior to grinding. Since it is almost completely soluble in hot water, the N content is therefore nearly all slow-release N. It has a calculated AI of 90 – 99 (ureaform: 55 – 65). Nitrogen is released from IBDU by hydrolysis, which is affected by soil moisture and temperature. Both urea molecules of IBDU can be liberated. The rate of N release is mainly a function of particle size: the finer the particles, the more rapid the rate of N release. IBDU is unstable in an acid media, whereby it decomposes into the starting materials. Therefore, it tends to release its nitrogen more rapidly in strongly acid soils. This can also be counteracted by using larger, well-compacted granules [158], [159].

The safety margin and agronomic response from IBDU is good with turf; occasional phytotoxity has been observed in greenhouse use. Since it is independent of microbial activity, IBDU is particularly suited to low-temperature application. Properties of IBDU are given in Table 22.

Table 22. Properties of CDU, IBDU, and Isodur

Property	CDU	IBDU	Isodur
mp, °C	245[a]	207 – 208	203 – 204[b]
Bulk density, kg/m^3	ca. 600	600 – 700	500 – 600
Solubility in water at 25 °C, g/L			
fertilizer grade		0.3 – 3.0	2.7
pure substance	1.3 (pH 2); 0.9 (pH 7)		1

[a] 259 – 260 °C for crotonylidene diurea (BASF).
[b] 236 °C for isobutylidene diurea (BASF).
[c] Toxicological data from BASF.

CDU (Crotodur). Crotonylidene diurea [1129-42-6] is a mixture of 75 – 80 wt % crotonylidene diurea (2 mol urea + 2 mol acetaldehyde) and 15 – 20 wt % 5-oxyethylcrotonylidene diurea [23048-84-2] (2-oxo-4-methyl-5-oxyethyl-6-ureidohexahydropyridine), 2 mol urea + 3 mol acetaldehyde), [145] and 5 – 7 wt % K_2SO_4.

Crotonylidene diurea

Manufacture. Crotodur, which was patented as a slow-release fertilizer in 1959 [153], is produced by acid-catalyzed reaction of urea with acetaldehyde (Chisso Corp., Japan) or crotonaldehyde (BASF, Germany) [154], [155]. The mother liquor is neutralized, and the CDU isolated as a white powder by spray drying or filtration.

Properties (see Table 22). CDU or Crotodur contains 85 wt % to > 90 wt % pure crotonylidene diurea. It is almost completely insoluble in cold water, but soluble in hot water with a calculated AI of 90 – 99. In contrast to isobutylidene diurea, N release from crotonylidene diurea depends on hydrolysis and microbial activity. Only the urea molecule from the side chain (6-position) can be liberated by hydrolysis. The urea which forms part of the ring can only be released by microbial action [146]. The particle size also influences the N release; with large particles, release is strongly delayed.

Application. In Japan and Europe Crotodur is mainly used on turf and in speciality agriculture, either as a straight N fertilizer or in granulated NPK fertilizers.

4.4.2.3. *Further Processing of Urea – Aldehyde Condensates*

All commercial urea – aldehyde condensates such as ureaform, IBDU, Isodur, CDU, and Crotodur can be further processed by compaction or moist granulation with other conventional fertilizers with rapidly available plant nutrients, thus producing straight and compound fertilizers with both slow-release and rapidly available nitrogen. However, it is necessary to keep the pH between 5.4 and 6.2 [147], or preferably between 5.0 and 5.5 [156], the temperature below 90 °C, and the dwell time as well as the quantity of recycled material as low as possible [130, pp. 1 – 15], [156] to prevent hydrolysis and, particularly in the case of ureaform, further condensation to higher oligomers.

Commercial Products and Trade Names. There are a large number of various slow-release fertilizers based on ureaform 38–0-0, methylene ureas 40–0-0, IBDU 31–0-0, and CDU 31–0-0, which are formulated as straight fertilizers and in combination with P, K, and secondary and trace elements in solid form, as well as in solutions or suspensions: Scotts Granuform, Scotts MU-40, ProGrow, ProTurf (The Scotts Company); Nitroform, Nutralene (Omnicology, Inc./AgrEvo); Plantosan, Nitroform, Nutralene, Azolon (Aglukon Spezialdünger). Hydroform, Hydrolene (Hydroagri US). Folocron, CoRoN (CoRoN Corp.); Isodur (Floranid), Crotodur (Triabon) (BASF); Azorit (EniChem); Urea – formaldehyde (Mitsui Toatsu Fertilizers); IBDU (Mitsubishi Kasei); CDU (Chisso).

Analyses of some typical fertilizers containing Isodur or Crotodur are listed in Table 23.

Table 23. Analysis and physical properties of typical fertilizers containing Isodur or Crotodur *

Property	Floranid permanent 15 + 9 + 15 (+ 2)**	Floranid N 32**	Triabon 16 + 8 + 12 (+ 4)**

4.4.3. *Other Organic Chemicals*

Some other organic compounds such as oxamide, triazones, and melamine have also been used as slow-release fertilizers but have not obtained the commercial importance of urea – aldehyde products.

Oxamide [471-46-5], the diamide of oxalic acid, N content 31.8 wt %, M_r 88.08, *mp* 419 °C, ϱ^{20} 1.667 g/cm^3, is a nonhygroscopic, colorless compound that forms needle-shaped crystals.

Its solubility in water is only 0.4 g/L [41, p. 320]. By hydrolysis in the soil, it is transformed first into oxamic acid with liberation of ammonia, and then into oxalic acid. Oxalic acid is toxic to plants if it is not further converted into carbon dioxide by microbial activity. Because the nitrogen is released by hydrolysis, the slow-release effect is primarily a function of particle size. Oxamide is manufactured by oxidation of hydrogen cyanide with hydrogen peroxide to give cyanogen, which is then partially hydrolyzed [161]. It can also be produced directly in one step from hydrogen cyanide, oxygen, and water, with copper nitrate as the catalyst [162], [163], [164].

In Japan, production of oxamide as a slow-release fertilizer amounts to about 1000 t/a (1995, Ube Industries) [165].

Symmetrical Triazones. Some symmetrical triazones are used as slow-release nitrogen fertilizers [160], particularly in urea – triazone solutions with 28 % N for application to soil. Triazones are synthesized by condensation reactions of formaldehyde or other aldehydes with urea, organic amines, or ammonia [131, p. 251].

Commercial Products and Trade Names. Hickson Kerley, United States: N-Sure 28–0-0, N-Sure-Lite 30–0-0, Trisert 13–3-4.

Melamine, triaminotriazine [108-78-1], is a high-nitrogen (66 wt % N) crystalline powder. It is produced through heating urea under pressure in the presence of a catalyst. Melamine slow-release fertilizer material is available as a powder (Nitrazine 66 % N). Currently only small amounts are used in the fabrication of slow-release spikes and stakes for shrubs and trees.

4.4.4. *Inorganic Compounds*

Some sparingly soluble inorganic compounds such as metal ammonium phosphates and metal potassium phosphates [130, pp. 256 – 284] are also used as slow-release fertilizers. Their solubility in water at 25 °C is [166], [167]:

$MgNH_4PO_4 \cdot H_2O$	0.014 g/100 mL
$MgNH_4PO_4 \cdot 6H_2O$	0.018 g/100 mL
$MgKPO_4 \cdot H_2O$	0.21 g/100 mL
$MgKPO_4 \cdot 6H_2O$	0.23 g/100 mL

The release of nitrogen, particularly from the two ammonium compounds, again depends on particle size (slow release only with larger particles or granules).

The manufacturing processes for magnesium ammonium and magnesium potassium phosphates are described in [130, pp. 256 – 284], [168], [169].

Other sparingly soluble inorganic compounds which have been used as slow-release fertilizers are based on crystalline ammonium potassium polyphosphates [170], and on glassy melts of ammonium dihydrogenphosphate, potassium hydrogenphosphate, and dicalcium phosphate [171].

Commercial Products and Trade Names. MagAmp (magnesium ammonium phosphate; Grace Sierra Horticultural Products); EnMag (magnesium ammonium phosphate + potassium sulfate; ICI).

4.4.5. *Coated and Encapsulated Controlled-Release Fertilizers*

Coated fertilizers are conventional soluble fertilizer materials whose plant nutrients are rapidly available and which after granulation, prilling, or crystallization are given a protective coating to control water penetration and hence the rate of dissolution and nutrient release in the soil. The AAPFCO definition is: “A product containing sources of water soluble nutrients, release of which in the soil is controlled by a coating applied to the fertilizer”.

Coated fertilizers are the fastest growing group of slow- and controlled-release fertilizers in the United States and in Japan. They accounted for 24 % of total world consumption of slow- and controlled-release fertilizers in 1995/96 [127, pp. 61 – 63]. The growth is due to improved economics in production, the possibility of controlling the release of nutrients other than nitrogen, and the greater flexibility in determining the nutrient release pattern.

Many condensation polymers, drying oils, waxes, and bitumen were tested for their suitability as coating materials [129, pp. 102 – 263], [172], [173]. However, only three categories of coated/encapsulated controlled-release fertilizers have gained commercial importance:

1. Sulfur coatings
2. Polymer coatings (e.g., PVDC copolymers, polyolefins, polyurethanes, urea – formaldehyde resins, polyethylene, polyesters, alkyd resins)
3. Sulfur – polymer coatings (hybrid products with a multilayer coating of sulfur and polymer) [174-186]

4.4.5.1. *Sulfur-Coated Controlled-Release Fertilizers*

The only inorganic coating material which has achieved any importance is sulfur [129, pp. 102 – 263], [132, pp. 151 – 169], [193-196]. The sulfur coating can be regarded as an impermeable membrane which slowly degrades in the soil through microbial, chemical, and physical processes. Nutrient release depends on the thickness of the coating in relation to the size of the granule or prill and the quality of the urea substrate. The total N content of sulfur coated ureas varies with the amount of coating applied; products currently available contain 30 – 42 % N, 6 – 30 % S, and various sealants and conditioners. Commercial production started in 1972 when ICI commissioned a pilot plant in the United Kingdom.

Manufacture. Most of the modern industrial processes are still based more or less on the technology developed in the 1960s and 1970s by TVA [193], [194], [197] (now National Fertilizer and Environmental Research Center). Preheated (71 – 82 °C) urea granules (1.7 – 2.9 mm) are introduced into a horizontal rotating cylindrical drum. Molten sulfur (143 °C) is sprayed onto the urea granules and quickly solidifies on contact. The average target thickness is 40 µm, but there are various random proportions of granules having thin (< 30 µm), medium (30 – 50 µm) and thick (> 50 µm) sulfur coatings. Any pores and cracks are closed in a second step by addition of a polymeric hydrocarbon/petroleum-based wax or a high-viscosity polymeric paraffin oil with a polyethylene sealant (2 – 3 % of total weight). A flow conditioner such as diatomaceous earth, talc, clay, or silica (2 – 3 % of total weight) is added to give a dust-free, free-flowing product with good handling and storage properties.

Other straight and compound fertilizers can also be coated with sulfur. However, ammonium nitrates and fertilizers with high contents of nitrate nitrogen are excluded due to the risk of explosion.

Agronomic Properties. Generally, sulfur-coated urea products have good slow-release properties. However, resistance of the coating to impact and abrasion is low. The quality of sulfur-coated urea (SCU) is characterized by the rate of N release into the soil solution within seven days (TVA method). SCU-30 indicates a product that releases 30 % of its nitrogen within seven days, resulting in a rather rapid initial effect. If coated too thickly they may exhibit lock-off, i.e., no effective nutrient release. These disadvantages of sulfur-coated conventional fertilizers were the reason for the development of sulfur-coated, polymer encapsulated fertilizers.

Commercial Fertilizers and Trade Names. Sulfur-coated fertilizers are mainly distributed as straight nitrogen grades, e.g., Enspan 39 % N (Hydro Agri, North America), sulfur-coated urea, and sulfur-coated potassium (Nu-Gro Canada).

4.4.5.2. *Sulfur-Coated, Polymer-Encapsulated Controlled-Release Fertilizers*

Sulfur – polymer hybrid coatings combine the controlled-release performance of polymer-coated fertilizers with the lower cost of sulfur-coated fertilizers. Figure 22 [198] shows the flow diagram of the process developed by RLC Technologies. The process yields a sulfur-coated controlled-release granular urea fertilizer with a uniform, durable polymer coating over the sulfur coating. The hot-melt polymer liquid sealant of the conventional process is replaced by specific liquid monomers. When applied sequentially onto the surface of the hot sulfur-coated urea granules, they copolymerize to form a firm, tack-free, water-insoluble polymer coating sealant. The liquid monomers used in this process are diisocyanates, such as MDI (4,4-diphenylmethane diisocyanate), and a polyol mixture of DEG (diethylene glycol) and TEA (triethanolamine); the TEA acts both as a reactive polyol and a catalyst. The resulting product has improved impact resistance. The RLC sealant provides a substantial improvement over polymeric wax and solvent-dispersed sealants [198].

Figure 22. Flow diagram of the RLC Technologies process

Commercial Products and Trade Names. The commercial products (in the United States) generally contain 38.5 to 42 % N, 11 to 15 % S and ca. 2 % polymer sealant: TriKote PCSCU 39–42N (Pursell Technologies), Poly-S PCSCU 38.5–40N (Scotts), and POLY PLUS PCSCU 39N (Lesco).

4.4.5.3. *Polymer-Encapsulated Controlled-Release Fertilizers*

Application of controlled-release fertilizers to high-value crops requires precise control of nutrient release geared to plant requirements. Hence, a range of polymer-coated controlled release fertilizers has been developed, in which the rate of nutrient release can be altered by means of the composition and thickness of the coating, giving longevities from one to 24 months. The release pattern of these controlled-release fertilizers is significantly more linear than that of PCSCU.

Polymer coatings can be semipermeable membranes or impermeable membranes with tiny pores. Most polymers used in coating conventional fertilizers decompose extremely slowly or not at all in the soil and leave residues of up to 50 kg ha^{-1} a^{-1}). This may be considered as an environmental disadvantage even though the accumulation of 10 years (500 kg) only represents 200 ppm in dry soil. Nevertheless, extensive research is being carried out into the development of polymer coatings that are biodegraded after application. In the case of polyethylene, polypropylene, and ethylene copolymers, incorporation of ethylene – carbon monoxide copolymer promotes photochemical degradation of the coating, and coatings that contain a poly(3-hydroxy-3-alkylpropionic acid) as active ingredient are biodegradable [178], [179], [185, p. 14].

Manufacture. In the *Sierra Process* [187] the coating material is a copolymer of dicyclopentadiene with drying or semidrying oils in an organic solvent (glycerol ester of linseed oil). The granules are coated with at least two layers in a coating drum operating at 65 – 70 °C. Maleic acid, for example, is added to improve the drying of the oil. Coating weights vary from 10 to 20 wt %; the commercial products are mainly blends of different coating weights.

The *Chisso Asahi process* [188], [189] produces a particularly smooth coating. The incorporation of finely powdered inorganic materials such as talc and silica into the coating [185, pp. 15, 16] makes it possible to produce controlled-release fertilizers in which the rate of release of nutrients in the soil varies with temperature. A hot 5 wt % solution of the coating material in a hydrocarbon or chlorinated hydrocarbon solvent is sprayed onto the warm granules of fertilizer in a fluidized bed, and the solvents are immediately evaporated with hot air (60 – 70 °C).

Polyolefins, ethylene – vinyl acetate copolymers, poly(vinylidene chloride), and mixtures thereof are used as coating material. The moisture permeability is modified by means of the ratio of ethylene – vinyl acetate (high permeability) to polyethylene (low permeability) [185, pp. 12 – 16].

The release pattern is determined by a water-leach test at 25 °C; for example, T-180 indicates that the product releases 80 % of its nutrient over 180 d at 25 °C in water. Products are produced from T-40 to T-360 [185, pp. 19 – 21].

The *Pursell Technologies Reactive Layers Coating (RLC)* process [190], [191] produces attrition resistant controlled-release fertilizers by coating a plant nutrient with a coating material that chemically bonds to it. Solvent-free polyols and polyisocyanates are pumped to nozzles, located along the entire length of a horizontal, cylindrical rotating drum. The two reactive liquids are applied sequentially in ultrathin layers onto the surface of preheated urea granules, where they polymerize directly to form a continuous polyurethane encapsulating membrane. The first layer of polyisocyanate can also react with the urea granule, chemically bonding the polymer coating to the surface of the urea granule. The thickness of the layer depends on the number of reactive layers and allows controllable release durations of up to 6 months to be achieved.

The polyols used in the process are predominantly polyester polyols. The isocyanates used are also a major factor in influencing the properties of the polyurethane encapsulation. Preferred isocyanate raw materials include polymeric diphenylmethane diisocyanates. Though the process had been primarily defined for the use of urea, most other plant nutrients/fertilizers can also be utilized.

Commercial Products and Trade Names. The main polymer-coated substrates are urea (40–0-0 and 38–0-0), potassium chloride/potassium sulfate, and NP, NK, and ammonium nitrate containing NPK fertilizers. Various grades also contain secondary and minor elements.

Trade names: The Scotts Company, US: Osmocote, Osmocote Plus (NPKs + MgO + TEs), High-N, Sierra, and Sierrablen; Prokote, Scottkote. Chisso Corp., Japan: Meister (urea, KCl and K_2SO_4) Lp and Long, Nutricote (NP, NK, NPK). Pursell Technologies Inc., US: POLYON lines (PC-U, PC-SOP, PC-NPK, PC-MAP, PC-KNO_3). Agrium, Canada: Duration and ESN (clay-coated PCU). Aglukon Spezialdünger, Germany (subsidiary of AgrEvo): Plantacote Depot, Plantacote Control (NPK), and Plantacote Mix. BASF, Germany: Basacote (NPK + TE). Haifa Chemicals, Israel: Multicote 4 (PC-NPK, PC-U, PC-KNO_3). Asahi Chemical Ind., Japan: Nutricote. Mitsubishi Chemical, Japan: M cote (PCU).

4.4.6. *Anti-Float Materials*

Special controlled-release fertilizers which sink immediately on application have been developed for application to irrigated crops. Diatomaceous earth or wetting agents such as liquid surfactants are applied to the external surface of the coated fertilizer to achieve this antifloat effect by breaking the surface tension between the water and the coated fertilizer [192].

Commercial Products and Trade Names. Pursell Technologies Inc. POLYON PCU-AF/AntiFloat, marketed in Japan by Sumitomo; Haifa Chemicals resin-coated anti-floating urea MULTICOTE.

4.4.7. *Controlled-Release Fertilizers on Carriers*

Bayer manufactures controlled-release NPK fertilizers based on water-insoluble synthetic ion-exchange resins [199], [200]. The nutrients are released from the resin granules by reaction with salts in the ground water.

Commercial Products and Trade Names. Bayer AG Lewatit HD 5 NPK 18–7-15 and Lewaterr 80 NPK (31–12–33).

4.4.8. *Supergranules*

A slow release of nutrients can also be achieved by granulation or compaction of conventional fertilizers with a relatively small surface to volume ratio (supergranules, briquettes, tablets or sticks or stakes). Some of these formulations also contain urea – formaldehyde or IBDU.

4.4.9. *Legislation*

In the United States, 50 states regulate their own agricultural policies, including fertilizers. There are some guidelines and Federal EPA regulations which can be imposed on the individual states (mainly concerning registration of pesticides under RECRA — Resource Conservation And Recovery Act — in the EPA). However, fertilizers are excluded [201]. In Western Europe there are not as yet general regulations of the EU Commission on slow- and controlled-release fertilizers, and there are no coated controlled-release fertilizers in the EU type list. There are regulations concerning definitions and classification in the individual member states. These cover fertilizer types such as coated urea, coated NPK, and partly coated NPK.

In Germany, CDU, IBDU and urea – formaldehydes (UFs) are classified as individual fertilizers. Legislation also includes the group of N, NPK, NP, and NK fertilizers containing UF, CDU or IBDU; other legislation covers coated and encapsulated fertilizers [202], [203].

To achieve European standardization, a Task Force slow-release fertilizers (TFsrf) has been formed with the aim of defining the conditions under which type of fertilizer included in the EU fertilizer type list can be newly categorized as a slow- or controlled-release fertilizer [127, p. 11]: A fertilizer may be described as slow-release if the nutrients declared as slow- (controlled-) release meet, under defined conditions including that of a temperature of 25°C, each of the following three criteria:

1. No more than 15 % released in 24 h
2. No more than 75 % released in 28 d
3. At least about 75 % released in the stated release time

This European Task Force has close contacts to the Controlled Release Task Force formed in the United States by AAPFCO (Association of American Plant Food Control Officials) and TFI (The Fertilizer Institute). In Japan registration of slow- or controlled-release fertilizers requires a dissolution test in water under well defined conditions [204], [127, p. 105].

4.5. Nitrification and Urease Inhibitors

4.5.1. *Introduction*

Ammonium ions in the soil — whether from decomposition of organic material or from the application of ammonia-containing mineral fertilizers — are oxidized to nitrite and nitrate. Bacteria of the species *Nitrosomonas* spp. are responsible for the transformation into nitrite. The nitrite is relatively rapidly oxidized to nitrate by *Nitrobacter* and *Nitrosolobus* spp., so that there is normally no toxic accumulation of nitrite in the soil [205, pp. 156, 157], [206, pp. 287, 289]. The process is known as nitrification. The formation of the environmentally relevant gases N_2O and NO may be regarded as a side-reaction of the nitrification process [207].

Nitrate is readily soluble in water and in the aqueous soil medium, and so is completely mobile in the soil, in contrast to ammonia, which is strongly adsorbed in soil colloids and base-exchange complexes. Therefore, it can be leached readily from the soil [208-212]. Under unfavorable (anaerobic) conditions nitrate can be reduced by denitrification to N_2 [206, p. 289]. This can result in further considerable losses of nitrogen [213, pp. 90 – 95].

Addition of a nitrification inhibitor to ammonia containing fertilizers or urea retards nitrification and minimizes leaching of nitrogen as nitrate and losses of nitrogen due to denitrification. Furthermore, nitrification inhibitors also suppress methane emissions and lower nitrous oxide emissions [207], [212], [214-218].

On application to the soil, amide nitrogen, as in urea, UAN (urea – ammonium nitrate solution), and some NPK fertilizers, is transformed by the enzyme urease via the unstable ammonium carbamate ($H_2NCOONH_4$) to ammonia, and CO_2 [205, p. 156].

This transformation has two major drawbacks:

1. It results in sometimes very high volatilization losses of ammonia when urea is applied to the surface [219], [220] or under flooded conditions.
2. It can produce severe seedling damage by ammonia and nitrite [221].

Urease inhibitors inhibit or reduce the formation of urease, which is ubiquitous in surface soils. This slows down the rate of urea hydrolysis in the soil and prevents or at least depresses the transformation of amide nitrogen into ammonia.

Definitions. *Nitrification inhibitors* are compounds that delay bacterial oxidation of the ammonium ion by depressing the activity of *Nitrosomonas* bacteria in the soil over a certain period of time. Thus, they control leaching of nitrate by keeping nitrogen in the ammonium form longer, and preventing denitrification of nitrate [222, p. 12]. *Urease inhibitors* prevent or depress transformation of the amide nitrogen of urea into ammonium hydroxide and ammonia over a certain period of time by inhibiting hydrolytic action on urea by urease; thus they avoid or reduce volatilization losses of ammonia.

There is considerable confusion concerning the terms nitrogen stabilizers, nitrification inhibitors, urease inhibitors, and stabilized fertilizers. The terms nitrogen stabilizers and nitrification inhibitors have been used interchangeably. Strictly speaking, stabilized fertilizers refers only to those which are modified during production with a nitrification inhibitor, such as ALZON and BASAMMON. In all other cases, fertilizers and nitrification and urease inhibitors are sold separately [222, p. 12].

Advantages and Disadvantages of Nitrification and Urease Inhibitors. Nitrification inhibitors significantly reduce leaching losses of nitrate by stabilization of ammonia [219], [220] and reduce emissions of the environmentally relevant gases N_2O and NO [207], [214-216], [223]. Nitrification inhibitors indirectly improve the mobilization and the uptake of phosphate in the rizosphere [224]. Urease inhibitors reduce ammonia volatilization losses, particularly from top-dressed agricultural fields and under reduced tillage conditions [225, p. 9, 10], [226-228]. Urease inhibitors furthermore reduce seedling damage where seed-placed levels of urea-containing fertilizers are too high [219], [221].

Possible disadvantages include the fact that fertilizers containing ammonia and a nitrification inhibitor may result in increased ammonia volatilization if they are not incorporated into the soil immediately after application. Depending on the type of nitrification inhibitor, the activity of soil bacteria may not only be interrupted for a certain time period, but the soil bacteria may actually be killed. This can be regarded an undesirable interference in a natural soil process [213, p. 219], [229, pp. 37 – 44].

4.5.2. *Types of Nitrification and Urease Inhibitors*

Extensive research on nitrification and urease inhibitors has been carried out mainly in Europe, Japan, Russia, and the United States. Various chemical fumigants and pesticides have also been tested to establish their possible effectiveness in inhibiting nitrification (nematicides; soil-insecticides and herbicides) [230, pp. 547 – 554].

Until the late 1960s research was carried out in the United States and Japan on N-Serve (2-chloro-6-trichloromethylpyridine; Dow Chemical Company), AM (2-amino-4-chloro-6-methylpyrimidine; Mitsui Toatsu Chemicals), Terrazole (5-ethylene oxide-3-trichloromethyl-1,2,4-thiodiazole; Olin Mathieson); ASU (1-amide-2-thiourea; Nitto Chemical Industry), and ATC (4-amino-1,2,4-triazole hydrochloride); substituted phenyl compounds (DCS), and compounds of the *s*-triazine line (MAST) [231, pp. 64 – 82]. In Eastern Europe and the former Soviet Union, CMP (1-carbamoyle-3-methylpyrazole) and its main metabolite MP (3-methylpyrazole) were tested extensively. However, only products based on pyridines, dicyandiamide, pyrazoles have gained practical agronomic importance as nitrification inhibitors. Terrazole, AM, and ASU (thiourea) had some regional importance, particularly in the United States and in Japan.

Reseach on urease inhibitors has concentrated on phosphoric triamides. Limited research has been carried out with PPD/PPDA (phenyl phosphorodiamidate) and ATS (ammonium thiosulfate) [222, p. 32].

There are no reliable statistics publicly available on the use of nitrification inhibitors due to the unique production structure. Estimates of the acreage treated with fertilizers containing nitrification inhibitors for the United States are 1860×10^6 ha (1995/96), 1660×10^6 ha thereof with nitrapyrin and 200 000 ha with dicyandiamide. For Western Europe a very rough estimate is 200 000 ha of arable cropland treated with fertilizers containing dicyandiamide [222, p. 63, 64].

4.5.3. *Pyridines*

4.5.3.1. *Nitrapyrin*

Nitrapyrin consists of 2-chloro-6-trichloromethylpyridine [1929-82-4] and related chlorinated pyridines, such as 4,6-dichloro-2-trichloromethylpyridine [1129-19-47].

Manufacture. The (trichloromethyl)pyridine compounds are manufactured by photochlorination of methyl-substituted pyridines. The desired amount of chlorine gas is passed through the appropriate methyl-substituted pyridine, generally in the presence of its hydrochloride. The product is recovered by conventional procedures such as filtration or distillation [232]. A flow diagram for the production of chlorinated picolines from readily available raw materials such as α-picoline is given in [233].

Nitrapyrin is produced exclusively by DowElanco in the United States and distributed under the trade name N-Serve (NS) [234-236].

Properties. Nitrapyrin is a white crystalline solid with a mild sweetish odor, *mp* 62 – 63 °C; *bp* 101 °C at 133 Pa. For use in agriculture nitrapyrin is formulated as a liquid product.

N-Serve 24 nitrogen stabilizer consists of 22.2 wt % 2-chloro-6-trichloromethylpyridine, 2.5 wt % related chlorinated pyridines including 4,6-dichloro-2-trichloromethylpyridine, and 75.32 wt % Xylene-range aromatic solvent [64742-96-6].

N-Serve 24E nitrogen stabilizer consists of 21.9 wt % 2-chloro-6-trichloromethylpyridine, 2.4 wt % related chlorinated pyridines, 4,6-dichloro-2-trichloromethylpyridine, and 75.7 wt % Xylene-range aromatic solvent.

Both formulations contain 2 lb of active ingredients per gallon (≈ 240 g/L); NS24 is recommended for use with anhydrous ammonia (82 % N) and impregnation onto urea; NS24E for use with liquid fertilizers (aqueous ammonia, solutions) and with manure (slurry).

Nitrapyrin has a very selective effect on *Nitrosomonas* bacteria. However, this effect is not only bacteriostatic but also bactericidal, so that part of the population in treated soil is killed [213, p. 219], [236], [237].

Toxicity. The single dose toxicity of nitrapyrin is low; the technical material has a LD_{50} of ca. 1000 mg/kg of body weight in laboratory animals. It is slightly irritating to the eyes and skin and has a low vapor toxicity. The equivalent LD_{50} (oral, female rat) for the two formulations is 2140 mg/kg (N-Serve 24) and 3300 mg/kg (N-Serve 24E). In soil and in plants, nitrapyrin is chemically and biologically rapidly degraded into 6-chloropicolinic acid, the only significant chemical residue from its use, and further to N_2, Cl^-, CO_2, and H_2O.

Application. The recommended application rate is 1.4 – 5.6 L/ha. In warm soils the nitrification inhibiting period is normally 6 – 8 weeks; it can be 30 weeks or more in cool soils.

However, in agronomic use this long-term standard nitrification inhibitor has two drawbacks:

1. Loss by volatilization from treated fertilizers during storage
2. The bactericidal effect, which may be regarded as an undesirable interference in a natural soil process

The loss by volatilization restricts it to simultaneous application with anhydrous or aqueous ammonia or fertilizer solutions which are injected directly into the soil at a depth of at least 5 – 10 cm. This limits acceptance in regions where nitrogen fertilizer is not commonly injected. Therefore, N-Serve is available commercially only in the United States.

4.5.3.2. *Other pyridines*

3,6-dichloro-2-trichloromethylpyridine is a proven nitrification inhibitor [238]. However, it is not readily obtained by ring chlorination of a 2-substituted pyridine because such chlorinations are not sufficiently selective to produce a preponderance of the desired isomer. Hence, 3,6-dichloro-2-methylpyridine is prepared by the addition reaction 1,1-dichloro-2-propanone and acrylonitrile to give 4,4-dichloro-5-oxohexanenitrile. Subsequent cyclization in the presence of hydrogen chloride gives 3,6-dichloro-2-methylpyridine, which is chlorinated to obtain 3,6-dichloro-2-trichloromethylpyridine [239].

Commercial Products and Trade Names. N-Serve 24 Nitrogen Stabilizer, N-Serve 24E Nitrogen Stabilizer, DowElanco.

4.5.4. *Dicyandiamide*

Dicyandiamide [461-58-5] exists in two tautomeric forms (⟶ Cyanamides – Dicyandiamide). Its nitrification-inhibiting property was first reported in 1959 [240].

Manufacture. All large-scale production processes are based on calcium cyanamide. In the first step cyanamide is liberated from calcium cyanamide by carbonation in aqueous solution at pH 7 – 8. The cyanamide is then dimerized to dicyandiamide at pH 9 – 10.

$$CaNCN + H_2O + CO_2 \rightarrow H_2NCN + CaCO_3$$

$$2\,H_2NCN \rightarrow H_2N-C=NCN$$

The dicyandiamide is isolated by filtration or centrifugal crystallization.

The disadvantage of this production process is the high energy input for the production of calcium carbide, the raw material for the production of $CaCN_2$; this is reflected in the relatively high price for the product as a nitrification inhibitor. There are only three major producers worldwide: SKW Trostberg and SKW Stickstoffwerke Piesteritz in Germany; Odda Smelteverk in Norway; and Nippon Carbide in Japan. The former Canadian producer, Cyanamid Canada, has ceased production.

Properties. Dicyandiamide is generally supplied as white or colorless crystals in paper or jute bags. Under dry conditions it can be stored for an unlimited period. It has low water solubility (3.2 g/100 g water at 20 °C) and contains at least 65 % nitrogen. When applied to the soil it is decomposed (partly abiotically and partly biotically by specific enzymes) and converted via guanylurea and guanidine to urea, a conventional fertilizer [241-244].

Dicyandiamide has a bacteriostatic effect on the *Nitrosomonas* bacteria. Depending on the amount of nitrogen applied, soil moisture, and temperature, the nitrification-inhibiting effect of dicyandiamide lasts 6 – 8 weeks.

Toxicity. With an LD_{50} of 10 000 mg/kg oral (female rat), dicyandiamide is practically nontoxic. The Ames test did not reveal any mutagenic activity. Furthermore, long-term studies have shown that dicyandiamide has no cancerogenity. Therefore, any risks for human health can be excluded. This also refers to its residues [237], [245].

Processing. In Western Europe the majority of ammonium-containing fertilizers are applied in solid form. However, a satisfactory nitrification-inhibiting effect can not be obtained by simple mechanical mixing of dicyandiamide with the solid fertilizer. Dicyandiamide added to the fertilizer prior to granulation, it decomposes at the usual granulation temperatures of 100 – 140 °C. When dicyandiamide is spread onto the finished fertilizer granules it does not adhere firmly to the granule surface. The use of vegetable, animal, or mineral oils as adhesion promoters has drawbacks with regard to storage and spreading. BASF has developed a process for applying dicyandiamide to ammonium- and sulfate-containing fertilizers without decomposition and with good adherence to the surface of the granules [246]. The fertilizer granules at 60 – 130 °C are mixed in a rotary drum with 2 – 4 wt % of finely ground dicyandiamide with simultaneous addition of a 40 – 50 wt % aqueous solution of $Ca(NO_2)$. The surface of the fertilizer material is rapidly cooled, thus preventing a decomposition of the applied dicyandiamide, which adheres well to the fertilizer granules.

Freeport-McMoRan Resource Partners in the United States has developed two processes for incorporating dicyandiamide into urea in combination with other nitrification- or urease-inhibiting compounds. In the first, dicyandiamide is incorporated into urea in combination with ammonium thiosulfate and a phosphate. Controlled release of N is claimed [247]. In the second, dicyandiamide is incorporated into urea in combination with *N*-(*n*-butyl)thiophosphoric triamide (NBPT) [248].

Application. Dicyandiamide is applied directly with N or NPK fertilizers and fertilizer solution, in which it is incorporated in correct proportion for the ammonia content. These stabilized fertilizers are recommended for all agricultural crops, particularly when grown on light-textured soils where heavy precipitation is expected within 6 – 8 weeks after application or where crops have a relatively slow growth rate during the early growing stages (e.g., potatoes).

Commercial Products and Trade Names. Ensan (BASF technical product); Basammon stabil (27 % total N, of which 1.6 % is dicyandiamide N (Ensan) and 13 % S); Nitrophoska stabil 12–8-17 (12 % total N, of which 1.1 % is dicyandiamide N (Ensan), plus 2 % MgO and 7 % S). Didin (SKW technical product); Alzon 27 (27 % total of N, of which 1.6 % is dicyandiamide N (Didin) and 31 % S); Alzon 47 [47 % total N, of which 3 % is dicyandiamide N (Didin)]; Piadin (SKW Stickstoffwerke Piesteritz) liquid mixture of DCD and 3MP (3-methylpyrazole, the main metabolite of CMP) in a proportion of 15 : 1, contained in Piasin 28/Alzon-flüssig (a urea – ammonium nitrate solution).

4.5.5. *Pyrazoles*

The group of pyrazole compounds has the largest number of compounds showing a nitrification-inhibiting effect [249], [250]. They include 3-methylpyrazole; 3,4-dimethylpyrazole; 4-chloro-3-methylpyrazole; 3-methylpyrazole phosphate; 3,4-dimethylpyrazole phosphate; 4-chloro-3-methylpyrazole phosphate; compounds resulting from the addition of polyacrylic acid to 3,4-dimethylpyrazole, 4-chloro-3-methylpyrazole, 3,4-dimethylpyrazole phosphate, 4-chloro-3-methylpyrazole phosphate; and from the addition of polyphosphoric acid to 3,4-dimethylpyrazole (1:20) and (1:1). In the 1980s and 1990s various compositions were patented [324], [251-256].

Properties. The nitrification-inhibiting effect of pyrazole compounds is better than that of dicyandiamide. However, they have one or more of the following disadvantages: they are liable to hydrolysis, which lowers the stability in storage and the activity period in the soil. They are too toxic and they are highly volatile. 3-Methylpyrazole is so volatile that significant amounts are lost when it is applied onto the surface of fertilizer granules or on fertilizer storages. Metal salts and metal complexes of 3-methylpyrazole [257] are also relatively volatile.

The most extensively tested pyrazole is 1-carbamoyl-3-methylpyrazole (CMP; in Russia: KMP). This compound is not as volatile as 3-methylpyrazole, but its manufacture is difficult and high evaporation losses may still occur when it is applied to fertilizers and on storage.

4.5.5.1. *1-Carbamoyl-3-methylpyrazole*

1-Carbamoyl-3-methylpyrazole (and its metabolite 3-methylpyrazole, MP) has the molecular formula $C_5H_7N_3O$.

CMP was developed by VEB Agrochemie Piesteritz (now SKW Stickstoffwerke Piesteritz, Germany). Further research and practical use was mainly carried out in the former German Democratic Republic, in Central Eastern Europe, and in the former Soviet Union.

Manufacture. Carbamoyl-3-methylpyrazole (CMP) is produced from 3(5)-methylpyrazole (MP) by carbamoylation with sodium cyanate in aqueous HNO_3. After 1 h, the resulting CMP is removed by filtration, washed with water, and dried in a vacuum dryer. The yield is 90 %.

Properties. Bulk density 630 kg/m^3, solubility in water 0.56 g/100 g, *mp* 123 – 125 °C, evaporation pressure 4.41×10^{-2} Pa (20 °C). Therefore, the technical solid product has to be transported and stored in closed containers. When mixed with solid or liquid fertilizers, these have to be applied and incorporated into the soil immediately after preparation of the mixture. CMP has a bacteriostatic but not bactericidal effect on *Nitrosomonas* bacteria.

Toxicity. CMP has an LD_{50} of 1580 mg/kg (rat, oral) and its metabolite 3MP and LD_{50} of 1312 mg/kg (rat, oral).

Application. For use in field testing and agriculture CMP was formulated as a 50 % CMP-preparation for mixing with solid ammonium-containing fertilizers or solutions. However, because of its liability to hydrolysis and to prevent evaporation losses the CMP formulation could only be added at the time of applying the fertilizer and, like nitrapyrin, had to be incorporated into the soil immediately.

Commercial Products and Trade Names. At present (1998) there is no registration for 1-carbamoyl-3-methylpyrazole or any other pyrazole compound as a nitrification inhibitor in Europe. In accordance with German fertilizer law, Stickstoffwerke Piesteritz has registered a 15 : 1 mixture of dicyandiamide with 3MP under the name Piadin, recommended for use with UAN fertilizer solutions.

4.5.5.2. *Outlook*

In recent years research has concentrated on overcoming the high evaporation losses on adding pyrazole compounds to fertilizer granules and solutions, on storing such modified fertilizers, and on applying them onto the soil. BASF [258] has reported a process in which fertilizer granules are covered with salts of 3-methylpyrazole and made resistant against abraision and evaporation by addition of an inorganic or organic polyacid [259]. This treatment significantly lowers the volatility of the nitrification inhibitor and allows smaller amounts to be used. The storage stability of fertilizers treated by the BASF process is also improved. In a test for 4 weeks at 30 °C, 40 – 50 % R. H., and 1.2 m/s air velocity on 3,4-dimethylpyrazole/polyphosphoric acid 1/20 and 1/1 (DMPP), losses of the applied nitrification inhibitor were 0 and 12 %, respectively. Thus, DMPP is of future interest as a nitrification inhibitor.

4.5.6. ***Neem/Neem-Coated Urea***

The extract from the press cake of the seed of the neem tree (*Azadirachta indica*) exerts a nitrification-inhibiting effect on *Nitrosomonas* spp. This effect is reversible.

The active compound in this biological nitrification inhibitor consists of various terpenes/triterpenes (epinimbin, nimbin, deacetylnimbin, salanin, azadirachtin, deacetylsalanin).

Toxicity. The formulated product is nontoxic.

Application. For practical use, a product containing 5.0 % active ingredient is to be mixed with urea in a ration of 1 : 100 before application.

Commercial Products and Trade Names. Nimin (5 – 5.5 % active ingredient) produced by Godrej Agrovet, Pirojshanagar (India).

4.5.7. ***Urease Inhibitors***

Although it has long been known that substantial evaporation losses in form of ammonia from urea may occur, it was only in the 1980s that the first chemical substances with effective urease-inhibiting properties in soils were disclosed, namely the phosphoric triamide compounds. Losses of between 3 and 40 % and more of applied nitrogen are possible when urea is not incorporated immediately after application and stays on dry soil (particularly on soil with a high pH and with high temperature). Also if it is applied with conservative tillage, particularly no-till, and on crops which are not tilled, such as bananas, sugar cane, oil palms, and rubber, as well as on flooded rice [206, p. 290], [213, p. 211], [218], [260-263], [264, pp. 52, 59]. Reference [265] lists 146 triamide compounds, of which *N*-(*n*-butyl)thiophosphoric triamide (NBPT) showed the best inhibition values.

N-(n-butyl)thiophosphoric triamide [94317-64-3], NBPT urease inhibitor is the best developed of the *N*-alkyl thiophosphoric triamide for commercial applications.

Manufacture. NBPT is prepared by a two-step synthesis in THF:

$$PSCl_3 + n\text{-}BuNH_2 + NEt_3 \rightarrow n\text{-}BuNHPSCl_2 + HNEt_3Cl$$

$$n\text{-}BuNHPSCl_2 + 4\,NH_3 \rightarrow n\text{-}BuNHPS(NH_2)_2 + 2\,NH_4Cl$$

The approximate product composition from this manufacturing process is as follows [337]:

- *N*-*n*-butylthiophosphoric triamide (NBPT), min. 85 wt %
- *N*,*N*-di-*n*-butylthiophosphoric triamide (DNBPT) 0 – 3 wt %
- *N*,*N*,*N*-tri-(*n*-butyl)thiophosphoric triamide (TNBPT) 0 – 3 wt %
- Thiophosphoric triamide (TPT) 0 – 3 wt %
- Others 0 – 10 wt %

– THF 0 – 2 wt %
– Triethylamine 0 – 2 wt %

Properties. Pure NBPT is a white crystalline solid, industrial grade NBPT is a waxy, sticky, heat- and water-sensitive material, which render this material difficult to handle. This material is susceptible to decomposition during storage and distribution. The vapor pressure is 1.1 kPa at 40 °C. The compound is an excellent urease inhibitor that inhibits the activity of urease for 12 – 14 d on dry soil. When incorporated into the soil in combination with urea or urea-containing fertilizers, it significantly reduces seedling damage when seed-placed levels of such fertilizers are too high [219], [221]. For satisfactory use on flooded crops, further research is needed. *N*-methyl-pyrrolidone (NMP) is a good carrier for NBPT [268]. However, cheaper formulations with better long-term stability are obtained with glycols and glycols with a liquid amine cosolvent [269].

Toxicity. The acute oral LD_{50} of NBPT is 1000 – 4000 mg/kg. The Ames tests were negative [266, p. 23]. The compound poses a very low acute toxicity hazard to workers and has received EPA approval. Because it inhibits free urease in the soil without affecting bacterial growth, it is not classified as a pesticide and hence not regulated under TSCA. In the soil, the product degrades into the fertilizer elements nitrogen, phosphorus and sulfur.

Application. For practical use in agriculture NBPT (Agrotain) is formulated as a green clear liquid containing [267] 25 % *N*-(*n*-butyl)thiophosphoric triamide, as active ingredient, 10 % N-methylpyrrolidone, and 60 – 65 % other nonhazardous ingredients. The recommended rate of application depends exclusively on the quantity of amide-nitrogen applied as urea, UAN, or in the form of NPK-fertilizers (1.4 kg per tonne of urea).

Agrotain is primarily recommended for pre-planting surface application of urea and urea-containing fertilizers, but may be used in pre-emergence, side-dress, top-dress, or other post-planting applications. It is not recommended for use if rain is imminent [222, pp. 38, 39].

Commercial Products and Trade Names. The only commercial product for use in agriculture is Agrotain (IMC-Agrico).

4.5.8. *Environmental Aspects*

In assessing the value of nitrification and of urease inhibitors not only must the better utilization of the applied nitrogen be taken into account, but also the possibility of maintaining clean ground water, as well as reduced emissions of ammonia and other environmentally relevant gases [222]. In Germany, where, in water catchment areas with restrictions or for other reasons, a reduction in applied nitrogen is required, the recommendation is that nitrogen application can be reduced by approximately 20 kg/ha without loss of yield.

Of equal importance are the positive environmental properties of nitrification inhibitors in significantly reducing emissions of climatically relevant gases such as N_2O and methane [207].

The application of urea or UAN-solution modified with a urease inhibitor such as NBPT would permit a substantial reduction in nitrogen losses to the atmosphere, and consequently also in the application rates, without affecting growth and yield of fertilized crops.

4.5.9. *Legal Requirements*

In Western Europe, there is no uniform regulation for DCD, the leading nitrification inhibitor (urease inhibitors are not yet in use). As in the case of slow- and controlled release fertilizers, individual countries [270], [271] have established national classification and legislation [272]. The pyrazole compound CMP (in combination with DCD) also comes under fertilizer legislation.

In the United States only fertilizers, but not additives to fertilizers, are excluded from RECRA (Resource Conservation And Recovery Act) regulations of the EPA. Therefore nitrapyrin — the active ingredient in N-Serve, the leading nitrification inhibitor in the United States — is classified as a pesticide in the EPA registration. In 1996 it was decided that all nitrification inhibitors have to be EPA registered as pesticides in the United States [222]. However, in spite of the new regulation, DCD will not require registration as a pesticide. NBPT, which does not affect soil organisms, is not classified as a biocide, but is regulated under the TSCA.

4.6. Organic Fertilizers (Secondary Raw Material Fertilizers)

At present an EC catalogue of commercial organic fertilizers is not available. Since these fertilizers mainly contain exploitable plant and animal wastes and in future will contain more waste of organic origin (with or without pretreatment such as composting, anaerobic fermentation, etc.), comprehensive legal provisions are in preparation. In Germany these organic fertilizers are designated secondary raw material fertilizers (*Sekundärrohstoffdünger*). According to the German Fertilizer Law their main components are organic waste materials for agricultural and horticultural utilization (secondary raw materials). These fertilizers are also subject to the German Waste Law (analysis of pollutant content, description of subsequent utilization) and the German Fertilizer Law (control of nutrient content) [273-275]. Depending on the quality standard, monitoring systems varying in analytic sophistication are specified. The main argument for the application of these fertilizers is the preservation of natural (and therefore limited) nutrient resources (e.g., P) by means of systematic recycling. The applied amount of these fertilizers is mainly limited by their nutrient content. In the case of low quality, the pollutant load can also determine the applied quantity. In Germany the permitted pollutant load conforms to the threshold values fixed in the decrees for the utilization ofsewage sludge (AbfKlärV), which are likely to be lowered substantially for reasons of soil protection [276]. According to the pollutant content or the ratio of nutrients to pollutants, organic wastes can be ranked as to their applicability as secondary raw material fertilizers (Fig. 23). For fertilizers containing several organic waste materials, each component must meet the legal requirements for secondary raw material fertilizers. Blending of unapproved material with compounds of low pollutant content is prohibited.

Figure 23. Applicability of wastes for agricultural use [277]

Another group of organic – mineral fertilizers are mixtures of fertilizer salts (N, P, K) with peat, composted bark, lignite dust, or, occasionally, dried slurry. The difference between these fertilizers and secondary raw material fertilizers is that the primary product of organic origin is not classified as waste. Nevertheless, threshold values for heavy metal concentrations have been set [e.g., 3 mg Cd/kg dry weight (dw); 750 mg Zn/kg dw]. In the case of peat, different combinations of fertilizer salts (N, NP, NPK, PK) are added. In the case of composted bark, lignite, or slurry, only mixtures with NPK fertilizers are supplied [274].

Organic fertilizers are also classified according to their effects:

– Fertilizers with an improving effect on soil condition have a stable organic substance as well as a slow effect on N supply (low concentration of readily available nitrogen)
– Fertilizers with short-term effects on nutrient supply, especially of nitrogen, have high contents of mineral nitrogen and/or readily available organic N compounds

Examples for the first category are composts (i.e. biogenic composts, garden composts) and fertilizers based on peat. The second category includes sewage sludge (high NH_4 concentration), blood meal, and potato starch wastewater (readily degradable organic N compounds).

Organic fertilizers with or without the addition of mineral fertilizer salts are classified as follows:

1. Fertilizers based on peat (or materials of similar stability): peat, composted bark, lignite
2. Fertilizers based on waste materials of animal origin: horns, bone meal, blood meal, hide meal, feather meal, guano
3. Fertilizers based on waste materials of plant origin (selected examples of waste materials from the food- and feedstuff industries): castor cake, cacao waste, brewer's grains, rape (marc), vinasse, spent mash, potato starch wastewater, filtration diatomaceus earth
4. Fertilizers based on municipal waste: sewage sludge, biogenic and garden composts

4.6.1. *Fertilizers Based on Peat or Materials of Similar Stability*

Peat (⟶ Peat) is an organic material of stable structure and low nutrient content that has no effect on nutrient supply without the addition of mineral fertilizers, but improves soil condition (e.g., aeration, water-retention capacity). The raw material for peat fertilizers is mainly highly decomposed upland moor peat (black peat) or acidic low moor peat (pH < 6). These peats (pH 3 – 5, volume weight 50 – 200 g/L, salt content 50 – 1500 mg/L, ash 2 – 15 %, organic matter 85 – 98 %) have high sorption capacity (cation sorption capacity 300 – 600 mval/L).

Depending on the kind of application, the crop, and the nutrient status of the soil, several mixtures of peat with mineral fertilizers (N, NP, NPK, and PK salts) are available. The following minimum requirements for nutrient content are specified: 1 % N, 0.5 % P, 0.8 % K, 30 % organic substance [274].

Similar mixtures of organic and mineral fertilizers are based on composted bark or lignite (partial substitute for peat) and other organic materials such as dried slurry or spent mushroom substrate (SMS). The minimum fraction of organic substance is set at 15 %. The organic substance of composted bark is highly stable against biological degradation and resembles the organic substance of peat. After complete decomposition, composted bark shows no N immobilization and is therefore suitable for replacing peat in mixtures with other fertilizers (pH 5 – 7, volume weight 150 – 300 g/L, salt content 100 – 1500 mg/L, ash 12 – 45 %, organic substance 55 – 88 %). Threshold values for heavy metal concentrations are specified for these fertilizers [274], [278].

4.6.2. *Fertilizers Based on Waste Materials of Animal Origin*

Only waste materials that pose no health risk may be converted into fertilizers. The raw materials arise as byproducts at butchers' shops, slaughterhouses, and carcass-disposal plants. Horn, bone meal, and blood meal are the most widely used in agriculture. In some cases, the primary products, containing mainly N and P, are upgraded by the addition of K salts [279], [280], [281], [282].

Horns. Horn materials (e.g., horns, hoofs, claws) consist mainly of the filament protein keratin. Since keratin decomposes slowly, horns represent a slow N source (22 % of the protein is in the form of cystein). The rate of N release increases with the extent of grinding (chips < grit < meal). Nutrient concentrations are listed in Table 24.

Table 24. Nutrient concentrations in fertilizers based on animal wastes (% in dry matter)

Fertilizer	N	P	K	Ca	Mg	C/N
Horn	10 – 14	0.4 – 4.0	0.2 – 0.8	1.5 – 7.5	0.5 – 1.0	3 – 4
Blood meal	9 – 13	0.2 – 1.0	0.2 – 1.5	1.5 – 3.0	0.4	2.4
Feather meal	12	0.3	0.2			4
Bone meal	4 – 6 (0.8)	7 – 12	0.2	18 – 25	0.6	4.5
Carcass meal	6 – 11	2.4 – 7.0	0.3 – 0.5	4 – 10	0.2	3.5
Guano	8 – 16	2 – 7	1 – 3	18	3 – 5	3 – 4

Bone Meal. Bones are ground, partly degreased, and cleaned. The main constituent of bone protein is the filament protein collagen (90 % of bone N is bound in collagen). By treatment with hot water and steam, collagen is converted into glutine and is removed. Therefore, steamed bone meal contains only 0.8 % N (untreated bones 4 – 6 % N). Due to the high P content (7 – 12 % P), bone meals are mainly applied as P fertilizers (Table 24). Occasionally, tricalcium phosphate is converted into monocalcium phosphate by acid treatment.

Blood Meal. Besides blood, blood meals often contain other slaughterhouse wastes such as intestine contents. These mixtures are dried and ground (N content 9 – 13 %; Table 24). Sometimes, mixtures of fresh blood (3 % N, 0.1 – 0.2 % P, 0.1 % K, 80 % water content) with solid wastes are used. Like meat meal, blood meal has a short-term effect on N supply.

Hide Meal. The main constituents of hide meal, a waste material from leather production, are skins and hair. The effect on N supply is quite slow (8 – 11 % N dw, C/N 5). In Germany, the threshold value for Cr^{3+} is set at 0.3 % in dry matter (for agricultural utilization, Cr^{6+} is prohibited in hide meal).

Feather Meals. These fertilizers show slow N release, comparable to that of horns. The N content of 13 – 14 % (Table 24) is mainly bound as keratin.

Meat and Carcass Meal. Occasionally, meat meal and carcass meal are converted into organic fertilizers. These slaughterhouse wastes have a high proportion of protein and hence a short-term effect on N supply (meat meal: 11 % N, 2.4 % P; meat-and-bone meal: 10 % N, 2.5 – 7 % P; carcass meal 6 – 10 % N; Table 24).

Guano consists of partially mineralized excrements of seabirds and can also contain feathers and carcasses. It is obtained from deposits in arid coastal regions of South America. Guano is converted to guano fertilizers by acid treatment. Guano fertilizers consist mainly of inorganic substances and contain 8 – 16 % N, 2 – 7 % P (ammonium and calcium phosphates) and 1 – 3 % K (Table 24). Since up to 50 % is in the form of ammonium, guano has a short-term effect on N supply.

4.6.3. *Fertilizers Based on Wastes of Plant Origin*

Provided the waste materials do not pose any health risk, conversion into fertilizers can be performed without special pretreatment. Both aerobic (composting) and anaerobic methods (fermentation, generation of biogas) are suitable for the treatment of plant wastes. The pretreatment and conditioning of some wastes are regulated. All substances described have low pollutant contents. Therefore, the applied quantities are only limited by nutrient contents [274], [281], [282]. The nutrient concentrations in these fertilizers are summarized in Table 25.

Table 25. Nutrient concentrations (% dw) in fertilizers based on wastes of plant origin

Fertilizer	N	P	K	Ca	Mg	org. S	C/N
Castor cake	5.5	0.8	0.8 – 1.6	0.4	0.3	80	8
Cacao waste	2.3 – 3	0.4 – 0.5	2.5 – 3.0	0.6	0.5	90	17 – 24
Brewers grains	4	0.4 – 0.7	0.5 – 1.0	0.3	0.2	65 – 75	10 – 12
Fruit pulp	1.0	0.3	1.3	0.8	0.1	85 – 95	40 – 50
Rape	1.5 – 2.5	0.4 – 0.8	3 – 3.5	1.0 – 1.8	0.2	75	20 – 30
Vinasse	3 – 4	0.15	6 – 7	0.6 – 1.2	0.3	50	8
Pulp	5 – 6	0.7 – 1.0	0.8 – 6.0			75 – 85	8 – 10
Potato starch wastewater	4 – 8 *	0.7 – 0.9 *	10 * – 12				5 * – 7
Filtration diatomaceus earth	0.7	< 0.1	< 0.1	0.2	< 0.1	6	4 – 8

* In fresh potato starch wastewater.

Castor cake is the residue of castor beans after oil has been pressed. Owing to its high protein concentration, castor cake contains 5 – 6 % N, which is ammonified in soil quite rapidly and thus becomes plant-available. The fertilizers are only traded in sealed packages due to their allergenic properties. Furthermore, the toxic substances ricin and ricinin must be destroyed by steam treatment at 120 °C for several hours, and dust has to be absorbed by treating

the castor cake with linseed oil.

Cacao waste is a residue of cocoa production and has a lower N and P content and higher K content than castor cake.

Brewers' grains (water content 75 %) and *rape* (water content 40 – 60 %) result as waste from brewing and from production of fruit juices and wine. They are used as fertilizers in fresh and composted form and have only a minor short-term effect on N supply.

Vinasse. Sugar-containing molasses is a waste material of sugar production from sugar beet. It is used for alcohol, yeast, and glutamate-production. The remaining sugar-free molasses is concentrated to 60 – 70 % and is then used as sugar-beet vinasse, an organic N and especially K fertilizer. Vinasse has a medium-term effect on N supply.

Pulp remains after alcohol production (distillery) from corn or potatoes (5 – 7 % dry matter). Potato pulp contains more K than corn pulp. Pulp has a medium-term effect on N supply, because potato and corn protein must first be decomposed by microorganisms. Ten cubic meters of pulp is equivalent to 30 – 40 kg N, 4 – 6 kg P, 5 – 40 kg K, and 200 – 300 kg C. Pulp is applied for fertilization as fresh material. Storage without addition of preservatives leads to unpleasant odors [283].

Potato Starch Wastewater. The production of potato starch generates large quantities of potato starch wastewater, which is used as a fertilizer. Depending on the production technique, 3 – 50 % of the total N is present in the ammonium form. Furthermore, the protein N is mineralized rapidly. Therefore, potato starch wastewater has a short-term effect on N supply. It also has a high K concentration. Potato starch wastewater is classified as follows:

- Fresh potato starch wastewater (ca. 6 % dry matter; 1 L is equivalent to 60 g dry matter, 5 g N, 025 g P, 6 g K)
- Treated potato starch wastewater (e.g., protein precipitation, evaporation, partly mixed with wastewater), 1 – 5 % dry matter (in the case of storable syrup, up to 55 % dry matter [284], [285])

Filtration diatomaceous earth is the filtration residue in breweries (75 % water content). Yeast proteins are the main N-containing substances. Owing to the narrow C/N ratio, this waste material has a short-term effect on N supply.

4.6.4. *Fertilizers Based on Municipal Waste*

This group is represented by biogenic and garden composts as well as by sewage sludge. In Germany the produced nutrient quantity of secondary raw material fertilizers is estimated at 270 000 t N per annum and 90 000 t P per annum, of which sewage sludge accounted for 60 % of N and 75 % of P. Composts accounted for 20 – 25 % of N and P. This demonstrates the importance of nutrient recycling by utilizing these waste materials as fertilizers. The precondition for recycling these wastes in agriculture and horticulture is a high quality standard, which strongly depends on the content of pollutants, especially heavy metals, dioxines, and furans. In Germany legal provisions for the utilization of sewage sludge and biocomposts have already been set or are in preparation (Waste Law, Fertilizer Law). These rules are likely to reduce environmental risks to a tolerable minimum and to promote the acceptance of the secondary raw material fertilizers [275], [281], [282]. Lately, sewage sludge and biocomposts have been classified as organic NPK fertilizers in the group of secondary raw material fertilizers [274].

Sewage sludge is mainly produced in municipal purification plants. Sewage sludge is classified into primary (residue after mechanical purification, deposits in settling tanks) and into secondary sludge (residue after biological purification by biomass and chemical purification by precipitation). Generally, the two kinds of sewage sludge are mixed and are subjected to various treatments. A precondition for the utilization of sewage sludge as fertilizer is an acceptable health standard. In Germany pollutant concentrations of sewage sludge have been considerably reduced over the last 20 years (e.g., Cd, Figure 24). At present, the average Cd concentration is 80 % lower than the threshold value specified in the decrees (AbfKlärV) for the utilization of sewage sludge (10 mg Cd/ kg dry matter) [276]. In 1993 dioxin and furan concentrations averaged 27 ng/kg, well below the threshold value of 100 ng/kg dry matter. Adjustment of the threshold values to the present quality standard is in preparation. In 1994 the average concentrations of heavy metals in sewage sludge applied in agriculture (in mg/kg dry matter) were Pb 84, Cd 1.8, Cr 56, Cu 251, Ni 32, Hg 1.6, Zn 977, all well below the permitted maximum loads set in the decrees for the utilization of sewage sludge (AbfKlärV) [276], [286].

Figure 24. Cadmium concentration in sewage sludge from 1977 to 1994 [286] (the dashed line marks the threshold value for agricultural use [276])

Depending on the pretreatment (dewatering; precipitation of P with Ca, Fe, Al salts; lime addition) nutrient concentrations in sewage sludge vary considerably (Table 26). Therefore, the nutrient contents of these fertilizers must be routinely monitored and adjusted if necessary. The short-term effect on N supply depends on the NH_4 content (fraction of total N). The effect on P supply depends mainly on prior precipitation and pretreatment (lime addition, drying). The applied amount of these fertilizers is determined by nutrient concentrations. For example, the input of P should correspond to the P removed by harvest. Thus the applied quantity remains under the maximum amount of 5 t dry weight of sewage sludge per hectare in three years.

Table 26. Dry matter and nutrient contents of sewage sludge (in wt %) [275]

	Dry matter	N	P	K	Mg	CaO
Range	6 – 23	2 – 6	1.5 – 7.0	0.2 – 0.5	0.4 – 0.7	0 – 15
Maximum	75	25	15			40
Average	12	3.8	1.6	0.3	0.6	

Biogenic and Garden Composts. Biogenic compost originates from biologically degradable waste, separated and collected in households. The portion of biologically usable waste in total domestic waste is 30 – 40 wt %. Garden compost consists of waste materials of plant origin such as litter or remains from pruning, collected in gardens, parks, and embankments and in National Parks. Composts represent the final product of a controlled rotting process in piles or bioreactors. According to the extent of rotting, composts are characterized as fresh or mature composts. Biogenic wastes are subjected to biogas production and subsequent composting.

As a result of the separate collection of the organic wastes, biogenic composts have lower pollutant concentrations than composts based on total domestic wastes (Table 27). Heavy metal concentrations of biogenic and especially garden composts remain under the threshold values set in the decrees for the utilization of biogenic composts (BioAbfV, in preparation). Average concentrations of organic pollutants (e.g., dioxins, furans) of 10 – 15 ng TE/kg dry weight lie within the range of the unavoidable natural background load from the atmosphere. Nutrient concentrations of composts vary less than those of sewage sludge but still have to be routinely monitored (Table 28). Garden composts have lower nutrient contents than biogenic composts. Compared to sewage sludge (high N and P levels) composts have high K contents and mainly a soil-meliorating effect. The short-term effect on N supply is quite low (only 10 % of total N is represented by mineral N). An effect on N supply is barely detectable after applications for several years. The maximum quantity of compost application is likely to be restricted to 20 t (30 t in case of high quality , i.e., minor contents of heavy metals) dry weight over three years per hectare [i.e., 100 (150) kg ha^{-1} a^{-1} of N) [287], [289], [275].

Table 27. Heavy metal concentrations in composts originated from domestic, biogenic and garden wastes (mg/kg dry matter) [287], [288]

Element	Domestic waste	Biogenic waste	Garden waste	Maximum concentration (BioabfV *)
Pb	286	55	59	100 (150) **
Cd	3.9	0.4	0.4	1 (1.5)
Cr	60	27	28	70 (100)
Cu	261	50	36	70 (100)
Ni	40	15	14	35 (50)
Hg	2.6	0.3	0.2	0.7 (1)
Zn	1020	201	133	300 (400)

* BioabfV: Bioabfallverordnung (German Biowaste Regulations), August 1998.
** Maximum quantity of compost application: 30 (20) t dry weight over three years per hectare.

Table 28. Nutrient concentrations in composts (% dry matter) [275]

Compost from	N	P	K	Mg	CaO	Salts (g/L)
Biogenic wastes	1 – 1.8	0.2 – 0.5	0.5 – 1.3	0.3 – 1.6	1.7 – 9.5	3 – 9
Garden wastes	1.0	0.2	0.6	0.5	8.5	(1 – 6)

4.7. Manure

There are four types of animal manures: solid manure, liquid manure, slurry, and dry manure from poultry. Solid manure consists of feces, urine, and bedding. Usually, *solid manure* contains 100 % of the feces; the fraction of the urine retained depends on amount and kind of bedding material, animal type, and the way of housing. The most widely used bedding material is straw, but it can also be peat litter or sawdust. *Liquid manure* contains the urine of the animal together with some rain water and cleaning water and small amounts of feces and bedding material. *Slurry* is a mixture of feces and urine with some additional water and some bedding and feed material. *Layer dry manure* consists of the excrement layers from battery farming.

Solid manure production is the most frequent animal manure handling system for raising young layers, broilers, turkeys, and cattle, the latter especially on smaller farms. For fattening pigs and cattle on larger farms, slurry systems have been favored in the last 30 years because production costs, especially labor costs, are lower.

4.7.1. *Composition [290-296]*

A major fraction of the nutrients consumed by animals is excreted with the feces and urine. For nitrogen, this is ca. 70 – 80 % of the intake, for phosphorus ca. 80 %, and for potassium 90 – 95 %. Table 29 lists the nutrient amounts produced per year by various animals.

Table 29. Nutrient amounts excreted per year from various animals

Animal	Nutrient amount, kg		
	N *	P_2O_5	K_2O
Milking cow (6000 kg/a milk yield)	110	38	140
Fattening cattle (125 – 600 kg live weight)	42	18	44
Sow with piglets	36	19	16
Fattening pig	13	6	6
Laying hens (100)	74	41	33
Fryers (100)	29	16	16
Turkeys (100)	164	81	71

*Excluding gaseous losses from storage or application.

The nutrient contents of manures are affected by type of feed, kind and amount of bedding material, amount of water supply, and kind and length of storage. Even for the same type of manure, the nutrient content can therefore show a wide range; deviations of more than ± 50 % from the average contents are possible. Table 30 lists the average content of organic matter, nitrogen, phosphorus, and potassium in various types of manures.

Table 30. Contents of organic matter and nutrients in various manures

Manure type and amount	**Organic matter, t**	**Nutrient amount, kg**		
		N	**P_2O_5**	**K_2O**
Solid manure, cattle, 10 t	2	54	32	70
Solid manure, pig, 10 t	2	80	80	60
Solid manure, fryer, 1 t	0.2	28	21	23
Solid manure, turkey, 1 t	0.2	23	17	16
Dry poultry manure, 1 t (50 wt % solids)	0.4	28	21	15
Slurry, cattle, 10 m^3 (10 wt % solids)	0.7	47	19	62
Slurry, pig, 10 m^3 (6 wt % solids)	0.5	56	31	30
Slurry, poultry, 10 m^3 (14 wt % solids)	0.9	98	83	48

4.7.2. *Manure Nutrient Efficiency[291], [294], [297-303]*

Availability of Nutrients. In animal manures, phosphorus, potassium, magnesium, calcium, and the micronutrients are predominantly present as inorganic compounds. Their plant availability is comparable to that of mineral fertilizers. The fraction of inorganic nitrogen depends on the type of manure (Table 31).

The organic nitrogen becomes partly available to the crop after mineralization in the soil. In the long run and under optimal conditions, liquid manure reaches a nitrogen fertilizer equivalent of up to 100 %, slurry 70 – 90 %, poultry excrement 60 – 70 %, and solid manure 50 – 60 %.

Table 31. Percentage of ammonium N and organic N in various manures

Type of animal	Type of manure	Percentage nitrogen as	
		Ammonium	Organic
Various animals	solid manure	15	85
Poultry	dried feces	30	70
Poultry	fresh feces	45	55
Cattle	slurry	55	45
Poultry	slurry	60	40
Pigs	slurry	70	30

As for all fertilizers, especially with regard to nitrogen, the nutrient efficiency of manures is highly dependent on the application conditions. Especially for slurry and liquid manure, spring application usually results in a much better nitrogen efficiency than autumn or winter application, especially in areas where nitrate leaching occurs over winter. Ammonia losses can be kept low if slurry is incorporated into the soil as soon as possible after application.

Humus Effect. As shown in Table 30, animal manures contain an considerable amount of organic matter. This organic matter may increase the organic matter content of the soil, depending on the application rate and the cropping system. Application of solid organic manures usually leads to a larger increase in organic matter content than slurry due to the bedding material, which is low in N and hence less readily decomposable. The application of organic matter improves soil quality in terms of water-retention capacity, turnover nutrient availability, and nutrient pore volume, and resistance to soil erosion.

4.7.3. *Environmental Aspects [294], [295], [298], [304-307]*

Environmental problems may result from inappropriate application of animal manures, especially at times when the crop does not require nutrients, at rates which exceed the nutrient demand, or if animal manures are not incorporated into the soil immediately after application. The consequences can be:

- Nitrate losses due to leaching after nitrification of ammonium N or mineralization of organic N
- Ammonia losses from the soil or crop surface
- Potassium losses due to leaching on light soils
- Phosphorous accumulation in the top soil and in the subsoil; phosphorus leaching from peat soils

With the aim of decreasing nitrate leaching into ground water, some countries have established legal regulations that restrict the amount of manure and/or timing of application (see Chap. Environmental Aspects of Fertilizer Application). A regulation to reduce ammonia losses from manure application and storage has been implemented in the Netherlands.

5. Fertilizer Granulation

Heinrich Dittmar

5.1. Introduction

The granulation of fertilizers was one of the most significant advances in fertilizer technology, affording considerable advantages to both manufacturer and user. Today, a well-defined grain size distribution is specified just as nutrient contents and good application properties are. Although the first granular fertilizers came on the market between 1920 and 1930, a stronger trend toward granulation developed — especially in the United States — only after the end of World War II.

In 1976, both granular fertilizers and bulk blends enjoyed shares of somewhat more than 40 % in the U.S. mixed-fertilizer market. Granular fertilizers were losing ground against bulk-blend products and liquid fertilizers [313]. In 1990, the corresponding figures are about 63 % for bulk blends, 22 % for liquid fertilizers and 15 % for granular fertilizers. In Europe, Africa, and Asia, granular fertilizers are the most frequently used form, far ahead of bulk blends and fluids.

Advantages of Granular Fertilizers. Forming and subsequent conditioning are indispensable for the production of fertilizers suitable for use. It was recognized at an early stage that fertilizers in powdered or finely divided form readily cake during storage. This is less of a problem with low-surface-area granules. Only free-flowing materials allow mechanized handling and distribution. Granules often require less storage space because of their greater bulk density: they are stored and transported more economically. A further advantage of granular fertilizers over powdered and crystalline products is that they tend to produce less dust, so that product losses are reduced. A granular product with a definite grain-size spectrum is a prerequisite for uniform mechanical application with field equipment (see Section Application): granules with diameters between 1 and 5 mm are most suitable. At the same time, losses caused by the wind, and the accompanying environmental problems, are dramatically reduced. Moreover, granules produced from various feedstocks (solids, slurries, melts) by granulation do not segregate, in contrast to bulk-blended products (Section Bulk Blending).

The use of granular instead of powdered fertilizers delays nutrient delivery to the plant until the granules have disintegrated completely (controlled delivery to the plant, diminished leaching losses). In the case of some controlled-release fertilizers, larger granules release nitrogen more slowly (see Section Slow- and Controlled-Release Fertilizers). Field studies in Swedish soils have shown that granular superphosphate with a grain diameter of 1 – 3.5 mm was twice as effective as finely-divided fertilizers [314], since the granular form retards phosphate fixation in the soil [315]. This reported effect varies with the soil type, the pH, the proportion of water-soluble P_2O_5 and the type of plant [316]. In the case of mineral fertilizers not containing P_2O_5 (N, NK, and NMg fertilizers), however, the grain size has only a slight effect.

Definitions [312, Chap. 1].

- Straight fertilizer: a fertilizer containing only one nutrient.
- Compound fertilizer: a fertilizer containing two or more nutrients.
- Complex fertilizer: a compound fertilizer formed by mixing ingredients that react chemically.
- Granular fertilizer: a fertilizer in the form of particles between two screen sizes usually within the range of 1 – 4 mm.
- Prilled fertilizer: a granular fertilizer of near-spherical form made by solidification of free-falling droplets in air or other fluid medium (e.g., oil).
- Coated fertilizer: a granular fertilizer that has been coated with a thin layer of some substance to prevent caking or to control dissolution rate.
- Conditioned fertilizer: a fertilizer treated with an additive to improve physical condition or prevent caking. The conditioning agent may be applied as a coating or incorporated in the granule.
- Bulk-blend fertilizer: two or more granular fertilizers of similar size mixed together to form a compound fertilizer.

Granulation Loop Granulation may be coupled with a production step, such as the manufacture of ammoniated triple superphosphate, or on the other hand it may be only a forming step in a production process, for example, granulation in the nitrophosphate process [317]. But other production operations also come

under the heading of granulation: the preparation of feed materials and, after forming, the steps of drying (Fig. 26), cooling, screening, comminution of material with too large a grain diameter (oversize), recycling of this comminuted material and of material with too small a grain diameter (undersize) to the granulator, and finally conditioning of the particles with the desired grain size (product fraction). The processing steps, linked into a loop by the recycle, are called the granulation loop (Fig. 25).

Recycling is carried out for the following reasons:

1. The size distribution leaving the granulator differs from the required distribution
2. The ratio of liquids to solids in the available feed is in excess of the requirements for the desired size enlargement
3. Granulated material is recycled to provide nuclei for the granulation process

Processes which correspond to (1) may be described as granulation efficiency limited; an example is the agglomeration of low-solubility fertilizers. Condition (2) is generally encountered where readily soluble or high water content feeds are agglomerated and can be described as liquid phase balance limited. Liquid phase balance frequently leads to high recycle rates with consequently high processing costs (Chap. Costs of Agglomeration). For the control of granulation see [318, p. 280]

Figure 25. Granulation loop

Figure 26. Drying drum, showing granulated product

Courtesy of BASF Aktiengesellschaft

The *granulation efficiency* often is defined as the mass fraction of particulate material that leaves the granulator as finished product, that is, with grain sizes in the desired range (assuming 100 % sieve efficiency) [317]. It is also possible, however, to state the granulation efficiency as the mass fraction of finished product at the dryer outlet [319]. This definition allows for some regranulation in the dryer. The mass ratio of material not withdrawn (recycled material) to product is often referred to as the recycle ratio. For example, a 20 % granulation efficiency implies a recycle ratio of 4 : 1 if other losses are disregarded.

The *recycle ratio* is important to the process of granulation. Recycle is necessary because, after the product has passed once through the granulator, a certain quantity of particles lies outside the desired region of the grain-size spectrum (off-size material) and must be run through again. For a given mixture and a given temperature, optimal granulation takes place only within a narrow range of the solid-to-liquid ratio. The quantity of recycled fines depends not only on the chemical properties of the materials but also on the water content of the slurry and on the granulation device [320]. Recycle is also needed to generate nuclei for agglomeration and to stabilize the granulation conditions in the granulator.

The quality of the granules is influenced by the following factors:

- Type and fineness of the feedstock
- Moisture content of the granules
- Surface tension of the wetting liquid and wettability of the particles
- Mode of motion in the granulator
- Inclination and speed of the granulator
- Type and properties of the binder

Granulation Processes. Granulation processes can be classified by the nature of the feed materials to be granulated (i.e., granulation of solids, slurries, melts [308, pp. 250 – 260], [313]) and by the type of granulation equipment used. The most important types of equipment for granulating fertilizers are shown schematically in Figure 27. For the most important fertilizer materials, both straight and multinutrient, Table 32 offers an overview of the main commercial granulation processes, along with further possibilities.

Table 32. Equipment for granulation of fertilizer materials * [317]

Fertilizer material	Granulation equipment: main commercial techniques are in boldface, while possibilities are in normal typeface
Calcium nitrate	prilling, flaking, pan granulator [322], drum granulator, compaction, pugmill/blunger [320]
Ammonium nitrate	prilling [308, p. 103], [323], cold spherodizer [323], [324], pan granulator [322], [323], [325], [326], drum granulator, fluidized-bed granulation [327], [328], spouted-bed granulation, TVA falling-curtain drum granulation
Calcium ammonium nitrate	prilling [309, p. 195], pugmill/blunger [308, p. 104], [309, p. 196], drum granulator, pan granulator [322], [329], hot spherodizer, cold spherodizer, fluidized-bed granulation [327], [330], spouted-bed granulation, TVA falling-curtain drum granulation
Ammonium sulfate nitrate	pugmill/blunger [309, p. 205], drum granulator [331], prilling [309, p. 205], pan granulator [332]
Ammonium sulfate	crystallization, hot spherodizer, compaction, pipe reactor-drum [333]
Urea	prilling [323], [328], [334] cold spherodizer [323], [324], pan granulator [322], [323], [325], [326], [335], crystallization, drum granulator [336], [337], compaction [338], fluidized-bed granulation [328], spouted-bed granulation [339], TVA falling-curtain drum granulation
Urea with ammonium sulfate	prilling [341, pp. 71 – 73], cold spherodizer, pan granulator [342], fluidized-bed granulation [340], spouted-bed granulation, TVA falling-curtain drum granulation
Superphosphate	drum granulator [343], pan granulator [309, p. 234], pugmill/blunger
Triple superphosphate	drum granulator [308, p. 191], [344], pan granulator [309, p. 348], pugmill/blunger [308, p. 191], [344], compaction
Monoammonium phosphate	drum/ammoniator-granulator [311, pp. 6 – 8], [345], [346], pugmill/blunger [311, p. 30], [347], prilling [311, p. 8], [347], crystallization, compaction
Diammonium	ammoniator-granulator [311, pp. 6 – 8], [345], [346], [348], crystallization, pugmill/blunger [346],

phosphate	[347], [348], compaction
Ammonium polyphosphate	ammoniator-granulator[311, p. 217], pugmill/blunger [311, p. 217]
Nitrophosphate (NP)	hot spherodizer, prilling [349], [350], pugmill/blunger [320], [351], pan granulator [332], [351], drum granulator [351], [352], fluidized-bed granulation
Potash	compaction [353], crystallization
PK	drum granulator [343], pan granulator, pugmill/blunger, fluidized-bed granulation [354]
Nitrophosphate (NPK)	hot spherodizer [324], [355], [356], prilling [349], [350], pugmill/blunger [320], [346], [355], [356], pan granulator [357], drum granulator [345], [346], [351], [355], [356], fluidized-bed granulation, compaction [317]
Compounds on ammoniacal base	drum/ammoniator-granulator, pugmill/blunger, hot spherodizer, prilling
Compounds with ammonium nitrate	ammoniator-granulator, pugmill/blunger, hot spherodizer, drum granulator, prilling
Compounds with urea	drum/ammoniator-granulator, pugmill/blunger, hot spherodizer, compaction, prilling
Compounds with micronutrients	ammoniator-granulator, pugmill/blunger, hot spherodizer, drum granulator, compaction

* Compaction is illustrated in Figure 34. The equipment for the other processes is illustrated in Figure 27.

5.2. Granulator Feedstocks

Granulation of Solids with Water or Aqueous Solutions. A solid phase (dry mixed nongranular or powdered material) and a liquid phase or steam (granulation aid) are required. Steam is discharged under the bed of material at the feed end, and water is sprayed on the bed through spray nozzles. For each mixture there is a percentage of liquid phase at which granulator efficiency is optimum. The higher the temperature, the less water and hence less drying is required [308, p. 251]. The system is granulation-efficiency controlled. Granulation takes place by agglomeration of the particles. The granulation efficiency is high and the recycle ratio is low (roughly 1 : 1). Examples are the granulation of superphosphate (with and without simultaneous ammoniation), the granulation of superphosphate in the presence of $(NH_4)_2SO_4$ and K_2SO_4, and the granulation of monoammonium phosphate together with other nutrients [313] to yield high-analysis formulations. While the granulation of solids has proved to be a flexible and economical process, it has the drawbacks of diminished quality as to physical properties and appearance. What is more, the P_2O_5 component (monoammonium phosphate or superphosphate) has to be prepared in a separate plant [313]. For an example of granulation with a solid P_2O_5 component, see [358], [359]; for granulation of NPK fertilizers containing urea, see [360].

Slurry Granulation. The materials to be granulated are in the form of a slurry, usually derived from reaction of sulfuric, nitric, or phosphoric acid with ammonia, phosphate rock, or a combination thereof. In some process modifications, solid materials may be added to the slurry before or during granulation (Fig. 28). Slurry granulation is liquid-phase controlled. Usually a thin film of a slurry having the fertilizer composition is sprayed onto small solid particles. The granules are built up in layers (layering process). The process is mainly controlled through the recycle and the slurry water content (the recycle ratio may be 5 : 1 or more [313]). Granulation is aided by various impurities (Al/Fe compounds, organic substances); see [320]. Drying can be combined with granulation into one processing step. A modification of the slurry process is the Spherodizer process developed by C & I Girdler (Section Drum Granulator). Slurry granulation is widely practiced in Europe for the production of N, NP, and NPK fertilizers. In the United States, the process has been modified so that acids, phosphoric and/or sulfuric, or partly neutralized acids are completely ammoniated in the granulator (ammoniator – granulator, Section Drum Granulator) [361]. For example, $(NH_4)_2SO_4$ can be granulated in a drum by this method [414].

Figure 28. Slurry granulation process [317, p. 23]

Granulation with solutions or slurries includes fluid-bed spray granulation (mechanism of agglomeration [362], [363]) and spray drying. In the continuous fluid-bed spray granulation process, solutions, suspensions, or melts can be converted to a granular product in a single step [364]. In contrast to spray (flash) drying, this process can be made to yield granules with a particle size of up to 5 mm [365]. The liquid for granulation is sprayed through nozzles located in or above the fluid bed onto the particles, which comprise comminuted oversize or undersize from the cyclone separator. Warm air in the fluid bed promotes the drying of the particles, and the sprayed particles increase in size. If melts are sprayed into the bed, cold fluidizing air carries off the heat of solidification. Fluidization is accomplished by blowing air through a plenum with a grid. Agglomeration with urea, NH_4NO_3, and K_3PO_4 has been reported [362].

Spray or flash drying represents a direct path from the liquid product to granules. The end product ranges from a powder to a fine grit. The feed liquid is atomized hydraulically, through feed nozzles, or pneumatically, with two-fluid nozzles or atomizer disks. The solution is sprayed into a tower-like vessel with a hot air stream and thus solidified into the fine granules. The dry product is removed pneumatically and collected in a cyclone system, or it can be removed with a bucket wheel at the bottom of the tower [366]. A few special fertilizer products are made by spray drying.

Fluidized-bed methods include the NSM process (Fig. 29) [327], [328], [370, pp. 277 – 288]. The granulator is a rectangular vessel with a perforated plate at the bottom to provide a uniform distribution of air. The fluid bed, which is initially made up of fines, has a height of 0.5 – 2 m and an area of several square meters. It is subdivided into chambers to obtain a narrow gradation in the end product. The granulation liquid or melt is sprayed into the fluid bed in each section by air. Heavier particles, which remain in the bottom portion of the fluid bed, can pass into the next section or to the outlet. In this way, the granular product migrates through the fluid bed from the first to the last section. The NSM plant has a capacity of 800 t/d for urea, and the production costs are less than those for prilling. For the properties of slurry granulation processes, see [367], [368]; for studies on the layering process, [369]. For fluid-bed granulation, see [363].

Figure 29. NSM fluidized-bed granulator [327, p. 7]

A modification combining granulation and drying in a variant of the fluid-bed process is the “spouting-bed granulator” [313], [371], [372]. The conical vessel stands on end, with a Venturi tube at the bottom, the narrowest section; into this section, either hot air propels a hot saturated solution or cold air propels a melt. The fluid bed is set up in the cone. The fast-moving particles require no perforated distributor plate. Drying or cooling takes place rapidly, and the material builds up in onion fashion. The dust collected in the cyclone is recycled (2 : 1 recycle ratio) [313]. Granulation tests on ammonium sulfate in the spouted bed have been reported [373]. Despite successful pilot tests, no full-scale unit has yet been built [371].

Melt Granulation. Spherical agglomerates produced from the melt (e.g., urea and ammonium nitrate) are called prills. These are usually obtained by spraying a salt melt or a highly concentrated solution into the top of a tower. The melt should have a very low viscosity (< 5 cP) but a high surface tension at temperatures just a few degrees above the melting point [374]. The liquid jet breaks up into droplets in the free air space. As they fall in contact with counterflowing cool air, the droplets solidify. The tower height (and thus the falling distance) and the velocity of the cool air are adjusted so that the prills are sufficiently hard when they strike the bottom of the tower [329]; tower heights are typically 45 – 55 m for ammonium nitrate [396]. The prills can be removed with scrapers or belt conveyers, or they can be cooled in a fluid-bed cooler located at the bottom end of the prilling tower [375]. Alternatively, the heat of crystallization can be carried away by spraying the droplets of melt into an oil bath. This is done, for example, with calcium nitrate [376], which is subsequently centrifuged and screened [377].

The recycle ratio in prilling is ca. 0.1 – 0.2 [315]. The prill, with a diameter of 1 – 3 mm, is usually smaller and rounder than the particle obtained by granulation. Because of the high air throughputs in the prilling space and the resulting off-gas problems, and also because of the smaller particle size, prilling has lost importance [315]. For small capacities, such as 250 t/d, granulation is economically superior to prilling; for high capacities, from 1000 t/d up, conditions determine which process is more economical [315], [378]. SCHOEMAKER and SMIT present a comparison between granulation and prilling in the manufacture of fertilizers [379]. For the prilling of NPK mixtures consisting of NH_4NO_3, $NH_4H_2PO_4$, and KCl, see [374].

For tests of oil prilling of a urea – ammonium sulfate mixture (34–0–0–9S), see [341, pp. 71 – 73], [342]; for tests of oil prilling of urea – ammonium polyphosphate mixtures, see [382]. Monoammonium phosphate can be obtained in melt form with a pipe reactor and sprayed into a prilling tower (Swift process) [347].

Multinutrient fertilizers mostly have high melting points and are very viscous [313]. One exception is a mixture of monoammonium phosphate and ammonium nitrate, which melts at a low temperature and has a low viscosity. The melt is granulated in a drum (recycle ratio 1 : 1). Depending on whether KCl is added in the granulator, formulations such as 24–24–0 and 17–17–17 are obtained. In a TVA process [380], phosphoric acid and NH_3 are reacted in a T reactor to yield an anhydrous melt; this can be granulated by itself to an ammonium phosphate/ammonium polyphosphate mixture (from 11–55–0 to 12–57–0) [313], or urea can be added to obtain a 35–17–0 or 28–28–0 granular product. If KCl is added, 19–19–19 can be produced [313], [381]. Granulation takes place in a drum or a pug mill (cf. Sections Pug Mill and Drum Granulator).

Melt-granulation processes have the advantage that a dryer, which is otherwise the largest and most expensive unit in granulation plant, can be dispensed with [308, p. 256]

5.3. Granulation Equipment

The condition for granulation is that a bed of solid particles moves, with simultaneous intensive mixing, in the presence of a liquid phase. This motion provides the particle collisions and bonding needed for granule growth. There are many types and models of granulating equipment, most of which use one of three basic intensive mixing mechanisms [321]:

1. Rotation of one or more shafts carrying staggered paddles in a fixed trough (pug mill, blunger).
2. Rotation of the whole device, such as drum or pan.
3. Movement of particles by a third phase, as by blown air in a fluid-bed granulator. In slurry granulation the third phase is usually hot air or hot combustion off-gases, which can serve as a drying medium at the same time. In this way, two processing steps in the granulation loop can be carried out in a single apparatus [365].

In order to improve pelleting conditions or pellet qualities, binding agents can be added along with the granulation liquid. The binding agents may be solid or liquid, may form films, crusts, or crystals, and may harden at standard temperature or at higher temperature [383].

Because granules can also be obtained by dry compaction, the compactor should be considered as a granulator here.

Various authors have reported data on granulators [309], [317], [321], [352], [384-388]. RIES has attempted to classify granulating equipment and processes [366], [389-391].

The granulating devices used most often in the fertilizer industry are drums, pans, and pug mills. While fluid-bed granulation has come into use in the fertilizer field, mixer – granulators and compactors are more frequently employed to form fertilizer granules. Spray drying and extrusion processes are used only for special fertilizer products.

5.3.1. *Pug Mill*

A pug mill (Fig. 27 A) consists of a U-shaped trough and, inside it, one or two shafts bearing strong paddles staggered in a screw-thread fashion. In frequency of use, two-shaft pug mills are dominant [317]. The shafts rotate at equal speeds in opposite directions in the horizontal or slightly inclined trough. The solid particles (fresh feed plus recycle) are fed in at one end of the trough and are thrown up in the middle of the trough, where they are wetted with the granulation liquid. In the trough, the paddles move, knead, and transport the moistened particles toward the discharge end. The particles can be given a better-rounded external shape either in a downstream tumbling drum or in the feed zone of the drying drum. Placement of a perforated NH_3 inlet pipe (sparger) at the bottom of the trough makes it possible to ammoniate and agglomerate the fertilizer at the same time. The pug mill is sturdy and can adapt to variable service conditions; it produces hard granules of uniform composition [321]. If the angle between the paddles and the shafts is optimized, the energy consumption can be reduced. The paddles are usually provided with a wear-resistant coating to prevent abrasion [320]. Processes have been described for granulating in a pug mill an ammonium polyphosphate melt (12–57–0), and the same melt with urea (28–28–0) [380], and the same with KCl (19–19–19) [341]. For tests on 35–17–0, see [392]. The combination of a pipe reactor with a pug mill for the granulation of NPK has been reported [393].

5.3.2. *Drum Granulator*

The drum granulator (Fig. 27 B and Fig. 30), which is the type of granulator in widest use for fertilizers, is an inclined rotating cylinder. The rotation speed is usually adjustable. For a given drum and a given granular product, there is an optimal peripheral speed that gives the highest yield of granules.

Figure 30. Drum granulator

Courtesy of BASF Aktiengesellschaft

An inclination of up to 10° from the horizontal ensures adequate movement of product toward the discharge end. Because, however, this inclination is not enough to effect classification, the discharged product has a fairly broad grain-size distribution, in contrast to the pan-granulator product (Fig. 31A).

Figure 31. Schematic representation of granule development in the drum granulator (A) and pan granulator (B) [394]

Drums in which the lengthwise axis is inclined upward from the feed end to the discharge [395] give a narrower particle-size spectrum. Such an upward inclination also increases the drum fillage.

In drums currently used in the fertilizer industry, the length-to-diameter ratio is ≥1 and may reach 6 : 1. The feed end may have empirically designed distributing elements on the inside wall to spread the feed material. In the adjacent part of the drum, where the granulation liquid is fed in, a good tumbling motion should be ensured. This can be achieved with light lifting flights, but they must not lift the granulate too high. In the remainder of the drum, the pregranulated material should be tumbled to a round shape and further compacted. This is also achieved with light flights on the wall and an appropriate fillage. The fillage in the spray and tumbling areas can be controlled by means of internal ring dams. The cylinder may be either open ended or fitted with ring dams at the ends [396] to prevent overflowing at the feed end and to control the bed depth and thus residence time. Fixed or movable scrapers inside the drum or hammers or other rapping devices outside on the drum can be used to remove or reduce excessive product caking inside the drum. Some material buildup on the drum wall may promote granulation [397]. Cylindrical drums are used for continuous granulation with and without internals.

As in the case of the pug mill, recycled product (undersize) generates a moving bed of material in the drum; a slurry containing, say, 3 – 8 % water can be sprayed onto the bed [309].

Powdered feed materials (mixed and wetted in an upstream mixer if necessary to provide granule nuclei) can be granulated in the drum through spraying with water, solutions, suspensions, and highly concentrated slurries, or through blowing with steam. The bed volume should be 20 – 30 % of the cylinder capacity [398]. The recycle ratios for drum granulation are generally between 1 : 3 and 1 : 6. Optimization of these plant parameters for each product class is done by trial and error.

The drum granules are better rounded but less dense than the pug-mill granules [321]. Drums 4.5 m in diameter and 16 m long are in use in the fertilizer industry.

An important modification of drum granulation is the TVA ammoniator – granulator (Fig. 27C and Fig. 32) [308, pp. 250 –260], [399-401]. This is a drum roughly equal in length and diameter, with ring dams at the ends but no lifting flights. Ammonia reacts with phosphoric and sulfuric acids below the surface of the tumbling bed of fresh feed and recycle. The reaction generates heat, which vaporizes the water at the same time that granulation takes place. The heat is removed by injected air. The ammonia and the acids are supplied to the bed through perforated distribution pipes mounted parallel to the drum axis. The requisite bed depth is ensured by the ring dam at the drum discharge. In a modern process, a mixture of phosphoric and sulfuric acids and ammonia is neutralized in a pipe-cross reactor situated upstream of the granulating drum (Fig. 33). The slurry is then fed to the drum along with recycle. While more phosphoric acid is sprayed onto the tumbling bed, ammonia is fed into the bed [313]. In this way, NPK fertilizers can also be produced [335, pp. 44 – 48]. In the SA CROS process for monoammonium phosphate production, phosphoric acid and ammonia are mixed and reacted in a pipe reactor. The slurry is distributed over the tumbling bed together with the steam generated; no subsequent ammoniation takes place in the bed [402]. For granule improvement with an interstage pan, see [403]. The use of the pipe reactor in combination with the granulating drum for the manufacture of granular ammonium phosphates was introduced by TVA in 1973 [311, p. 45] and was later incorporated in many plants [404]. A possible improvement in the drum granulator is represented by the double-pipe granulator, which is especially well-suited to fertilizer mixtures with a high proportion of recycle (Scottish Agricultural Industries system, Fig. 27 E) [309], [405]. For example, by virtue of the high recycle ratio with corresponding residence times, a hard ammonium nitrate – ammonium phosphate mixture can be granulated.

Another modification of the drum granulation process described is the spray-drum process (Spherodizer, Fig. 27D). In a rotating drum, preneutralized slurry is sprayed onto a dense curtain of granules cascading from baffles inside the drum. The water content of the slurry must be, say, 12 – 18 % to allow good spray dispersion [309]. During granulation, hot combustion gases flow through the drum in cocurrent [406], so that drying takes place at the same time. The dried particles are then sprayed again, redried, and so forth. The grains grow in shell fashion with an onion structure and are very hard. Spherodizer units are built in capacities of up to 650 t/d. Such an apparatus has a diameter of 4.5 m and a length of 12 m [309]. The Spherodizer, developed by C & I Girdler [407], [408], was first used on an industrial scale in 1959. The *cold* and *hot* used for the versions of the Spherodizer describe the condition of the air that flows through the drum. The cold version is used with melt feeds, especially ammonium nitrate and urea, while the hot version serves for granulation and spraying with slurries (NPK fertilizers, nitrophosphates, ammonium phosphate – nitrate, urea – ammonium phosphate) [317]. Granulation and drying thus take place in the same device. Under optimal service conditions, the recycle ratio is approximately 1 : 1.

A combination of drum granulation and fluid-bed technology is embodied in the Kaltenbach-Thuring Fluidized Drum Granulation (FDG) process [325, p. 39], [409], [410]. The technique is suitable for both melt and slurry granulation (e.g., size enlargement for urea and ammonium nitrate prills).

In a drum, the best granulation takes place at 25 – 45 % of the critical rotation speed [361], which is the rotation speed at which the weight of the granules and the centrifugal forces are in balance [386], [318, p. 204]:

$$N_{\mathrm{crit}} = 42.3\sqrt{\frac{\sin\beta}{D}}$$

D = drum diameter, m
β = drum inclination
N_{crit} = critical rotation speed, rpm

5.3.3. *Pan Granulator*

The tumbling motion of granules during agglomeration can also take place on a rotating inclined pan (Figs. 27 and 31 B).

For a given pan size, if the inclination of the pan axis to the horizontal is increased, the granules roll upward less steeply but have a longer residence time in

the pan. The granulation nuclei and the small granules initially move in the vicinity of the pan bottom. During granulation, the rotation of the pan and the force of gravity cause them to take up a spiral path. The particles grow and eventually reach the bed surface. The spiral diameter decreases continuously until the granules, finally becoming large enough, run over the rim of the pan (Fig. 31 B). Melts or slurries are often sprayed onto the bed, but water or solutions can also be used as granulation aids, and steam can be injected into the bed. If water is employed, it should be applied in the region of the largest spiral diameter [320]. Experience has shown that the spray liquid must be dispersed more finely, the finer the solids for granulation [413]. Because the overflow product has a rather uniform grain size, downstream classification can often be dispensed with. By means of an advancing and retreating scraper blade, the pan bottom can be kept fairly clean and the formation of crusts can be avoided. Here, as in the drum, some material coating the pan prevents wear and promotes the correct tumbling action [396]. The pan can also be made in the shape of a truncated cone or can have at its periphery a tumbling ring, onto which the granules fall from the pan rim; surface coating agents can be applied. Pan granulators are manufactured with diameters of up to 7.5 m [317]. Typically, the height of the rim is one-fifth of the diameter.

Concentrated salt melts of urea, ammonium nitrate, or calcium nitrate can be processed in the pan granulator; the products are easily applied fertilizer pellets, and an alternative to prills [322], [323], [383], [415].

For the production of granular triple superphosphate, phosphoric acid is added to digest finely milled crude phosphate in a granulator – mixer; this step yields a moist, crumbly product, which is directly processed in a subsequent pan to the required pellet size with the injection of steam and the addition of hot phosphoric acid [383]. For the pan granulation of urea – ammonium sulfate mixtures, see [342].

The relationship between the critical rotation speed and the pan diameter and inclination is the same as for the drum granulator [396].

In general, pan rotation speeds are $n \approx 0.6 – 0.75 n_{crit}$, where n_{crit} is the critical rotation speed; the pan axis is usually inclined at 45 – 55 ° to the horizontal [411]. According to the TVA [412], the optimal angle is ca. 65 °. The throughput of a pan granulator can be calculated roughly as follows [386]:

$$\dot{m} = k \cdot 1.5\, D^3$$

$\dot{m}$ = throughput, t/h
k = factor ca. 0.95 – 1.1 for mixed fertilizers
D = pan diameter, m

5.3.4. *The Granulator – Mixer*

While the pan granulator must be fed with powdered or pre-pelleted material, the granulator – mixer can accept friable, plastic, pasty, or crumbly feeds. If the mixing elements move at the proper speed, the material is comminuted to the desired grain sizes [383]. The disintegration of hard agglomerates is made possible by cutter rotors mounted at the sides of the mixing space [416]. Granulator – mixers are often used in batch operation, while pan granulators are run continuously. Process engineers in the fertilizer industry have also combined the two kinds of apparatus with the mixer upstream to improve product quality. The mixing vessel itself either has a fixed position or may rotate, while the movable mixing elements (e.g., mixing stars, spirals, shafts with attached vanes, plowshare mixing elements) effect intimate mixing and thus granulation by virtue of their rotation. The shape and rotation speed of the mixing elements are usually variable and can be adapted to a range of mixing and granulation jobs. Wear of the mixing elements must be expected. The mixing vessel proper can have a variety of shapes: smooth pipe, zigzag rotary pipe, pan, cone, Y, tub, and so forth. The mixer is often provided with external auxiliary heating. The liquid used for granulation can be fed to the mixing space and distributed by means of a hollow shaft [385], but suitable openings and feed pipes on the vessel can also feed in the liquid. For granulation – mixing of fertilizers, the device has a specific energy consumption of 2 – 6 kW per 100 kg of product [417]. The granulation time can be taken as 5 – 10 min. Grain sizes between 0.1 and 5 mm are achievable. The capacity is up to 30 000 kg/h per mixer [366]. RIES compares the grain-size distribution curves of fertilizer granules from granulator – mixers with those of the starting fineness [418].

5.3.5. *Roll Presses*

The size enlargement of a finely dispersed charge material by external compression is implemented in press agglomeration (Fig. 34). The charge is gripped by two counterrotating rolls, nipped in the gap, and compressed. As the void volume decreases, the material generally undergoes a two- to threefold compaction. While a charge hopper is adequate for a free-flowing material, a material that is not sufficiently free-flowing can be transported to the nip by screw feeders, with some precompaction. If the rolls are smooth, the material exiting from the nip ("shell") has a smooth surface. If the rolls have mating depressions, briquetts are produced. The shells are next reduced to the desired grain size (in a crusher or mill) and screened. The fines and oversize are recycled (Fig. 35). Rolls are manufactured in diameters up to 1.4 m and widths up to 1.5 m [390]. They may be mounted side-by-side or over-and-under.

Figure 34. Press agglomeration with smooth rolls [386, p. 215]

Figure 35. Compacting of a multinutrient fertilizer [419, p. 34]

For the specific compressive forces for urea, KCl, and $(NH_4)_2SO_4$, see [353]; for data on the compaction of special fertilizers, [420], [421]; of K_2SO_4, [320]; of calcium cyanamide, [422]. For a general description of fertilizer compaction, see [423], [424]; for a monograph on roll pressing, [425]; for the principles of pressure agglomeration, [419].

5.4. Costs of Agglomeration

The costs incurred for granulation depend not just on the agglomeration properties, but — for equal or nearly equal agglomeration properties — on the size and type of equipment used in the process. For equipment and investment costs for pan granulators, drums, mixers, and roll-compaction equipment, and on hourly operating costs versus equipment size, see [426]. With regard to personnel, mixers and roll presses are considered to require one-half man (year-round, rotating shifts), while pans and drums are figured at one man each. In contrast to dry compaction (roll presses), drying costs have to be added in for mixer granulation. Up to a certain moisture content, mixer granulation with drying is quite competitive with dry compaction. For processes and costs of agglomeration, see also [427]. In comparing the granulation of solids and slurries, the investment costs are one-third higher for slurry granulation, and the operating and utility costs are likewise greater [313].

For production costs with various granulating equipment, see [428], [429]. For a cost and process comparison between prilling and granulating, see [378], [430]; for the costs of granulating monoammonium phosphate and diammonium phosphate, [311]; for the costs of NPK granulation in the Norsk Hydro nitrophosphate process, [349]; for the costs of fertilizer compaction, [431]. For economic aspects and comparative estimates of manufacturing costs, see [308, pp. 138, 266].

5.5. Bulk Blending

The mechanical mixing of single components in granular form, called bulk blending, is a special way of producing multinutrient fertilizers. Bulk blending was introduced in the USA at the beginning of the fertilizer industry [447]; it is not nearly so widespread in Europe. In the process, several of the usual starting

components, such as superphosphate, triple superphosphate, monoammonium phosphate, diammonium phosphate, urea, and potassium chloride, are combined in an uncomplicated device such as a rotating drum. The nutrient ratio can be adjusted as desired. The components are briefly mixed (up to 15 t/h) and made available to the farmer in batches that are usually loaded directly into the distributor.

The precondition for this process is that the components in the mixture be physically and chemically compatible [317], [448]. For example, urea and ammonium nitrate must not be present together, since a mixture of these is very hygroscopic and tends to deliquesce. Further, stoichiometric mixtures of urea and ammonium nitrate are sensitive to impact, and even a solution of the two can form an explosive mixture [449]. Mixtures of urea or diammonium phosphate with normal or triple superphosphate have only limited compatibility. If an aqueous salt mixture has a somewhat elevated pH and simultaneously contains NH_4^+ ion, NH_3 may be liberated.

Bulk blending has the drawback that segregation can occur during silo filling, packaging, transportation, and application. A uniform grain size or grain-size distribution is essential for reducing segregation, even if the particles differ in density. Design measures at the silo inlets and inside the silos can prevent segregation [335, pp. 37 – 39]. Drum mixing generates dust, which may necessitate cleanup measures depending on the amount of dust and the size of the mixing equipment.

The process has the advantages that the N : P_2O_5 : K_2O ratio desired by the farmer can easily be obtained; micronutrients, insecticides, and herbicides can easily be metered in, and the dealer requires less storage space.

For the production of bulk-blended urea with an appropriate gradation, see [370, pp. 277 – 288]. For the bulk-blending system in the United States, see [447], [450-452]; for the use of mechanical fertilizer mixing in Germany, see [453].

5.6. Quality Inspection

For successful handling and application, certain ranges of physical properties must be specified for the fertilizer particles. Quality control, which includes chemical analysis as well, is performed by the fertilizer manufacturer. For the determination of the physical properties of mineral fertilizers, see [308], [432-434].

Grain Shape. Fertilizer particles should have the least possible surface area, since irregular shapes lead to increased abrasion and a tendency to cake.

Grain-Size Spectrum. The diameter of ordinary commercial fertilizer grains is in the range of 0.5 – 6 mm. U.S. products generally have a somewhat finer size spectrum (primarily 1 – 3.35 mm) [317] than European products (primarily 2 – 5 mm). In exceptional cases, the product grains may be coarser, as in the case of a woodland fertilizer applied from the air (6 – 12 mm), or finer, as in the case of ammonium sulfate and crystalline mixed-salt fertilizers (< 2 mm) and other special fertilizers. The grain-size distribution is important for the intended application, for example to ensure uniform distribution of fertilizer nutrients by field equipment. The grain-size spectrum is determined by screen analysis (ISO 8397 standard screening). For the grading curves of granular fertilizers in comparison to the starting fineness, see [418].

Settled Density. The settled density is important for the sizing of packaging equipment and storage areas. For a given fertilizer grade, it should fluctuate as little as possible. The settled densities of granular fertilizers can be determined in accordance with ISO 3944; those of finely divided fertilizers (with a high content of <0.5 mm), in accordance with ISO 7837.

Compacted Density. The compacted density is generally as much as 10 % higher than the settled density. It represents the maximum bulk density that can be achieved through vigorous shaking. The compacted density can be measured in accordance with ISO 5311.

Dumping Angle. The dumping angle (angle of slope) of a fertilizer is important for the design of storage areas and for transportation. The dumping angle should be as large as possible and can be measured in accordance with ISO 8398.

Grain Hardness. The grain hardness is a measure of the fracture strength of fertilizer grains and their mechanical stability in storage. As a rule it is measured by placing grains of a definite size between two parallel plates and compressing [435].

Abrasion Resistance. The abrasion resistance is a measure of the mechanical stability of fertilizer grains moving against one another and of their stability in free fall (wear due to tumbling and dropping). Abrasion causes dusting of the fertilizers during storage operations, transportation, and application. The abrasion resistance should be as great as possible and can be determined with, for example, the TVA method [308].

Caking Tendency. One of the most important properties of a fertilizer is its storability, which can be determined through measurement of its tendency to cake. By careful drying and effective surface treatment (see Section Fertilizer Conditioning), the caking tendency can be significantly reduced and thus the storage qualities improved. This property is measured by, for example, a shear test on caked fertilizer.

Hygroscopicity. The hygroscopicity of a fertilizer characterizes its sensitivity to atmospheric humidity. Grains of a highly hygroscopic fertilizer exposed to sufficiently high air humidity take up moisture, which impairs their initial grain hardness and abrasion resistance. The hygroscopicity of a fertilizer is assessed from the water-vapor adsorption isotherm. The rate of water uptake and the critical relative humidity of the salt system can also be determined [434], [436]. Critical humidities are listed in [437]. Corresponding to the critical relative humidity is the partial pressure of water vapor over a saturated salt solution forming a very thin skin of liquid over the salt surface. If the humidity of the ambient air is less than critical, the liquid skin gives up water; if greater, the product gains moisture.

5.7. Fertilizer Conditioning

A conditioner is a material added to a fertilizer to promote the maintenance of good physical condition (flowability) during storage and handling. The use of conditioners is essential with many products, but is not required with all fertilizers. It is preferable to use other means, such as good drying, to avoid caking. Even if the fertilizer grains are dried adequately from an economic standpoint, caking may occur and impede storage, transportation, and field application.

Hardening and caking result from the crystallization of water-soluble salts and the formation of bridges between the grain surfaces during storage. The surfaces also suffer plastic deformation under pressure, and the reduction of the water vapor pressure in the joint between the new contact surfaces causes the particles to adhere to one another [438]. The reaction

$$NH_4NO_3 + KCl \rightarrow NH_4Cl + KNO_3$$

during storage may also be indirectly important in poor storage qualities [315, p. 370], [439].

The internal conditioning of fertilizers means incorporating additives in the granules before or during granulation to improve the physical properties and the anticaking qualities. Internal conditioners usually act as hardeners or crystal modifiers, for example to improve the storage properties of ammonium nitrate fertilizers. Internal conditioners inhibit or modify the effects of crystal phase inversions due to temperature changes during storage. The inversion at 32 °C can cause uninhibited ammonium nitrate granules and prills to shatter and cake. In the case of urea prills and granules, 0.2 – 0.5 % of formaldehyde or urea – formaldehyde is added to the urea melt as a hardener and anticaking additive [308, p. 301]. The addition of 1.8 % Mg $(NO_3)_2$ protects ammonium nitrate from caking. The destructure effect of the phase change at about 32 °C is avoided [440, p. 200].

External conditioning, also called coating and surface treatment, means applying to the granule surface a thin layer of powders or surfactants to reduce the caking tendency. The addition of wax and/or oil enhances the action by suppressing dust formation. This process step is carried out in a rotating drum or a fluid bed. Although coating with a fine, inert powder (kieselguhr, talcum, lime, kaolin) has long been practiced as an external form of inorganic conditioning, surface treatment with nonionic organic sealants (polyethylene waxes, paraffins, urea – aldehyde resins) and coating with surfactants to make the grain surface hydrophobic came into use later. The surfactants employed are, above all, fatty amines and sulfonates. These are also used [315] in combination with powders and waxes and/or oils [370, pp. 289 – 303]. For the use of special oils as anticaking agents, see [441]; for an example of a surfactant, [442]. For special coatings to prevent caking, see [443]. Because of the many anticaking agents and fertilizers in production, no overall recommendation can be made as to special additives for general use [438].

Intentional aging of fertilizer in a storage pile prior to bagging or bulk shipment is referred to as curing. In products that benefit from curing, chemical reactions that cause caking bonds apparently proceed to near completion during the curing period. The heat of reaction retained in the curing pile speeds the completion of the reactions. After curing there is reduced tendency for additional bonds to develop [308, p. 302]. In the manufacture of superphosphates, pile curing for about 30 d frequently is employed to improve physical properties.

5.8. Environmental Aspects

In fertilizer plants, the gaseous effluents from all equipment handling solid materials, including screens, have to be cleaned owing to their content of fine dust (and harmful gases). Although the most serious dusting occurs during the drying of granular fertilizers, dust is also formed in the granulators. These units are therefore operated under a partial vacuum. The dust in the off-gas is usually collected in cyclones and recycled. When dry dust collection is inadequate, wet separation in scrubbers, which also absorb gases like NH_3, is employed. Recycling of the scrub waters is implemented in the AZF process [444]. For NPK fertilizers, experience has shown that a soft granular product has a stronger dusting tendency than a hard one. For certain fertilizer formulations, less dust is produced from the drum than from the pug mill [445].

Gaseous effluents like ammonia, nitrogen oxides, and fluorine compounds are evolved in the production of NPK fertilizers and feedstocks. Normally these exhaust gases are scrubbed, and the resulting scrubber liquors are recycled to the process.

Liquid or aqueous effluents from fertilizer plants are usually of smaller volume compared to those vented to the atmosphere [308, p. 322]. They generally result from scrubbing equipment and can be concentrated and recycled. Spills and washings are usually collected in floor sumps and also concentrated and recycled.

For the removal of emissions from fluid-bed granulators, see [370, pp. 277 – 288]; for fluorine emission in triple superphosphate production, [446]; for a summary of environmental practices in the fertilizer industry, [308, pp. 319 – 328].

6. Analysis

Vilmos Czikkely and Titus Niedermaier

The point and purpose of fertilizer analysis is to check the declared fertilizer grade and confirm that the contents of grade-determining components, nutrients, nutrient forms, nutrient solubilities, and incidental components are as printed on the bag. In the Western countries, all fertilizers are subject to official inspection, and the laws permit only small deviations within given limits.

In nearly every country, only products with established compositions and analyses are allowed in trade; therefore, inspections must be performed during production, and factory laboratories must use testing methods in compliance with the established official techniques of analysis (Table 33)

Table 33. National and international standards for fertilizer analysis

Method	European Economic Community [454]	Federal Republic of Germany [455]	International Organization for Standardization [456]	United States (AOAC) [457]
Sampling and sample	No. L 213 on pp. 2 – 4	No. 1.1, 1.2, 1.3	ISO 3963; ISO 5306;	No. 2.1.01 – 2.1.05
preparation (see Section Sampling and Sample Preparation)	EN 1482	DIN/EN 1482	ISO 7410; ISO/DIS 7742	
Nitrogen analysis (see Section Determination of Nitrogen)				
Total nitrogen	No. 2.3; § 7.1 in No. 2.6.1; § 7.2 in No. 2.6.2	No. 3.5 (3.5.1 – 3.5.5)	ISO 5315	No. 2.4.02 – 2.4.06
Ammonia and nitrate N	2.2 (2.2.1 – 2.2.3)	No. 3.3 (3.3.2 – 3.3.4)	ISO 11 742	No. 2.4.09 and 2.4.10
Ammonia N	No. 2.1; § 7.2.5 in No. 2.6.1 and § 7.5 in No. 2.6.2	No. 3.2.1 – 3.2.6	ISO 5314, ISO 7408	No. 2.4.07 and 2.4.08
Nitrate N	§ 7.2.4 in No. 2.6.1 and § 7.4 in No. 2.6.2	No. 3.4.1 and 3.4.2	ISO 4176	No. 2.4.11 and 2.4.12
Urea N	§ 7.2.6 in No. 2.6.1, § 7.6 in No. 2.6.2	No. 3.8 (3.8.1 – 3.8.5)	ISO 8603	No. 2.4.20

Sulfur	No. 8.1, 8.2, 8.4, 8.5, 8.9		ISO 10 084	No. 2.6.28
Micronutrients	No. 9.1 – 9.11	Chap. 8 (8.1.1 – 8.9.2)		No. 2.6.01 – 2.6.04, 2.6.10 – 2.6.16, 2.6.22 – 2.6.25, 2.6.29 – 2.6.32

6.1. Sampling and Sample Preparation

Sampling must produce a sample that corresponds to an exact, representative average of a large product batch. The most appropriate time for fertilizer sampling is during bagging or when the bulk product is being loaded into conveyances. Only when sampling at this time is impossible should samples be taken from closed bags or from a bulk product stockpile. As a rule, the sample taken should make up at least 0.1 % by weight of a batch for delivery. Fertilizer regulations also contain provisions for sampling methods. A minimum requirement is given in EN 1482.

A suitable sample divider is next used to reduce the sample quantity to some 1 – 2 kg. The final sample must be prepared for analysis by comminution, screening, and homogenizing. The smallest portion called for by the analytical technique must still be representative of the whole final sample. At the same time, this preparation must not alter the gradation of the fertilizer in such a way as to have a marked effect on typical properties such as the solubility in extractants.

6.2. Determination of Nitrogen

The most important nitrogen compounds are nitrates, ammonium salts, urea, urea – aldehyde condensates, and cyanamide. Farm-produced fertilizers (e.g., liquid manure) have most of their nitrogen in organic form (protein).

Total Nitrogen. The analytical method for determining total nitrogen is dictated by the components present in the fertilizer. For straight N fertilizers that contain only ammonia nitrogen, e.g., ammonium sulfate, it is sufficient to alkalize the sample solution and distill the liberated ammonia into an acid of known concentration in the receiving flask. For samples containing nitrate, on the other hand, the nitrate content must be reduced first. Examples of ways to reduce the nitrate are with iron or chromium powder in an acid solution, with ARND alloy in a neutral solution, or with DEVARDA alloy in an alkaline solution. Nascent hydrogen reacts with the nitrate to give ammonia in quantitative yield. Distillation from the alkalized reaction solution gives the sum of ammonia N and nitrate N.

For fertilizers that contain other forms of N besides ammonia and nitrate, the reduction step must be followed by the conversion of the other N forms (urea, cyanamide, protein) to ammonia by Kjeldahl digestion.

The final determination of total N in every case is by distillation of ammonia from the alkalized pretreated solution into a receiving flask with an acid standard solution and backtitration of the residual acid excess.

Ammonia Nitrogen Apart from Other N Compounds. In theory, the ammonia component is easily isolated from commercial mixed-salt fertilizers by distillation from sample solutions alkalized with NaOH or KOH. Urea and other organic N forms readily give additional ammonia in alkaline solution. If such compounds are present, the distillation conditions must be kept as mild as possible. The solutions are alkalized with soda, calcined magnesium oxide, or freshly precipitated calcium carbonate, and the ammonia liberated is distilled under reduced pressure at room temperature or with the help of a strong air purge.

For pure ammonium salts of strong acids, the formaldehyde method offers a quick procedure for ammonia determination. The reaction of ammonium ion with formaldehyde

$$4\,NH_4^+ + 6\,CH_2O \rightarrow (CH_2)_6N_4 + 6\,H_2O + 4\,H^+$$

liberates protons equivalent to the ammonium ions present; these can be directly titrated with sodium hydroxide standard solution.

Nitrate Nitrogen Apart from Other N Compounds. In many cases, nitrate N is determined as total N minus ammonia and urea N. The most versatile direct method is precipitation of the nitrate with nitron and final determination by gravimetry. Another sensitive method, recommended for specially formulated mixed fertilizers with low nitrate contents, is a colorimetric technique based on the nitration reactions with 2,4- or 3,4-xylenol. The nitration products give intensely colored compounds in alkaline solution.

Urea Apart from Other N Compounds. Three different methods are available for the selective determination of urea:

1. Separation of urea by precipitation with xanthydrol(9-hydroxyxanthene), yielding dixanthylurea; gravimetric final determination
2. Enzymatic hydrolysis of urea, controlled by ureases; distillation of produced ammonia into a receiving flask with acid standard solution, where it is absorbed
3. Colorimetric method (for low urea contents) based on the reaction of urea with *p*-dimethylaminobenzaldehyde

Nitrogen Fertilizers with Controlled-Release Urea – Aldehyde Condensates. Ureaform, Isodur, and Crotodur are nitrogen compounds that are only slightly soluble in cold water but are nonetheless effective as fertilizers. The delayed water solubility provides a basis for the analytical characterization of these compounds: extraction with cold water isolates the readily available N components (ammonium, nitrate, free urea). Only when the extraction residue is treated with hot water do isobutylidene diurea, crotonylidene diurea, and the short-chain components of the urea – formaldehyde condensates go into solution.

In an acid medium, especially at high temperature, condensates of urea with formaldehyde and with isobutyraldehyde tend to hydrolyze to urea and the aldehyde. In mixed fertilizers with an inherent acid tendency, there is thus a danger of altering the solubility characteristics in the course of the analysis. For this reason, the separations are carried out in buffered solutions of pH 7.5 [455].

To calculate the percent N contents, either the total N is determined in the extraction solutions or else the AOAC procedures for urea – formaldehyde condensates are carried out and a nitrogen activity index is determined.

$$\frac{\%\,\mathrm{CWIN} - \%\,\mathrm{HWIN}}{\%\mathrm{CWIN}} \times 100 = \mathrm{AI}\ \text{in}\ \%\ ,$$

where CWIN is cold-water-insoluble nitrogen and HWIN is hot-water-insoluble nitrogen.

The nitrogen activity index for urea – formaldehyde condensates is around 50; crotonylidene diurea and isobutylidene diurea have values of more than 90.

6.3. Determination of Phosphate

Because phosphorus fertilizers are rated by their contents of phosphate available to plants, various extraction methods have been devised.

Extraction with Water. Most countries define *water-soluble phosphates* as those components that go into solution at room temperature when an aqueous suspension is made with 1 g of sample to 50 mL of suspension volume (in the USA, 1 g of sample to 250 mL).

Extraction with Citrate Solution. The technique of citrate extraction determines phosphates, such as $CaHPO_4$, that are insoluble in water but soluble in complex-forming salt solutions.

The most common methods in Europe use ammonium citrate solutions with a prescribed citrate concentration. The officially approved extraction processes differ in the choice of pH. Extraction is performed in a strong alkaline medium with an ammoniacal ammonium citrate solution, or in a neutral ammonium citrate solution. Most often, extraction is carried on for 30 min at room temperature and is followed by a treatment at 40 °C; for the EEC process with neutral ammonium citrate solution, 65 °C is prescribed.

Extraction with Citric Acid Solution. Originally, the citric acid solubility was stated only for Thomas phosphate, but the lack of agreement between the plant availability of P_2O_5 and the solubility in ammoniacal citrate solution led to other straight and mixed phosphate fertilizers being rated by citric acid solubility. Treatment with 2 wt % citric acid solution (5 g of sample is agitated in 500 mL of citric acid solution for 30 min at 20 °C) dissolves phosphorus – silicon

heteropolyacids, which are hardly soluble in complex-forming salt solutions.

Extraction with Formic Acid Solution. Soft and hard phosphate rock can be distinguished by their behavior in 2 % formic acid. A 5-g ground rock sample is shaken at 20 °C for 30 min with 500 mL of the formic acid solution. In the case of soft phosphate rock, 50 – 70 % of the total phosphate dissolves; in the case of hard phosphate rock, only ca. 25 % dissolves.

Extraction for Total Phosphate Determination. A technique applicable to all fertilizers as well as crude phosphates is digestion with sulfuric acid, nitric acid, and copper sulfate. Mixtures of hydrochloric and nitric acids or nitric and perchloric acids have also been proposed for quantitative extraction.

Determination of Phosphate. After hydrolysis of polyphosphates in acid solution, if necessary, phosphate is precipitated as quinolinium molybdatophosphate and weighed. Possible substitutes for the gravimetric final determination are methods in which the precipitate, washed acid-free, is dissolved with an excess of sodium hydroxide standard solution and back-titrated with nitric acid standard solution. Reaction of the dissolved phosphate with a molybdate – vanadate solution yields a soluble, colored heteropolyacid complex, which can be determined by colorimetry.

6.4. Determination of Potassium

For almost all fertilizers that contain potassium, this component is dissolved in water. In complete fertilizers, it is advisable to perform the extraction in acid solution so that, if gypsum is present, none of the potassium will take part in double salt formation and remain undissolved as syngenite. For the determination, the potassium is precipitated with sodium tetraphenylborate from a weakly alkaline or acidic solution; the product, slightly soluble potassium tetraphenylborate, is weighed. Another proposal, mainly in the USA, is to precipitate the potassium as the chloroplatinate (AOAC). Flame photometry is also recognized as an official test method.

6.5. Analysis of Calcium, Magnesium, and Trace Elements

Complexometric methods with EDTA have come into widespread use for determining calcium and magnesium. Photometric techniques for the determination of other metal ions effective in growth (Cu, Fe, Mn, Zn, Co, Mo) have been described. To an increasing extent, however, atomic absorption spectrophotometry has gained in importance. Emission spectral analysis with plasma excitation is also used in fertilizer analysis. But this procedure is new, and as yet no official analytical specifications exist for it.

Boron must be isolated by distillation in the form of methyl borate before it can be determined. The boric acid is reacted with 1,1-dianthrimide or azomethine H, and the colored product is determined by photometry. For boron contents of 0.1 % and higher, boric acid and polyhydric alcohol (usually mannitol) are reacted to give didiolboric acid, which is determined volumetrically.

[Top of Page]

7. Synthetic Soil Conditioners

Reinhardt Hähndel and Hans Prün

Soil conditioners are substances with which the soil and substrate properties, seldom ideal for the growth of plants, can be optimized and stabilized. Their purpose is to exert biotic, chemical, or physical influences on soils in such way as to improve the soil structure and water regime [462]. Synthetic soil conditioners have well-defined composition, stable quality, and properties suited to the requirements they must meet. They may, for example, supplement or replace natural substances that are unsuitable from an environmental and ecological standpoint, are in scant supply, or must be conserved.

7.1. Foams

Foamed polystyrene and foamed urea – formaldehyde resin are used as soil conditioners; foamed phenolic and polyurethane resins are used as florists' mounting media or plant growth media [458].

7.1.1. *Closed-Cell Expandable Polystyrene Foam*

Expandable polystyrene (PS) foams consist of polystyrene pre-expanded by blowing agents at temperatures of about 100 °C and, after holding, expanded with steam. The forms used for soil conditioners are flakes, beads, or raspings [458-460], [463], [464].

Physical and Chemical Properties. Expandable PS foams have closed cells. They contain 98 % air by volume and can hold 1 – 2 % water on their surface [465], [466]. They do not, however, absorb water. Air exchange does take place [467]. Styromull foam flakes are 4 – 16 mm in diameter with a loose density of 12 – 20 kg/m^3 [459]. The permeability to water between expandable PS flakes without compression is roughly the same as that of fine gravel; under 25 % compression, it matches that of coarse sand; at 75 % compression, that of fine sand.

Expandable PS foams are largely resistant to attack by acids and alkalies; they are odorless, chemically neutral, and unobjectionable to plants. These foams have been considered resistant to degradation by soil bacteria. Physical degradation takes place under the action of ultraviolet radiation, and biodegradation, especially by soil fungi, yields carbon dioxide and water [467]. This process is slow, however, so that the foams are effective soil conditioners with a relatively long lifetime.

Raw Materials. ⟶ Styrene.

Use. Expandable PS foams in comminuted form for soil application have been described [468], [469]. Uses range from incorporation into soils and garden substrates to the conditioning of weak-structured peat [470].

Incorporated, they have soil-loosening, aerating, and draining actions. Foams are also employed as soil conditioners in crop farming and landscaping, and they have proved useful as drainage aids in slit drainage and as filter materials for covering drain pipes [458], [471], [472].

For soil aeration and structural stabilization around the roots of urban trees, expandable PS foam beads (1 – 2 mm diameter) are recommended for use with soil aeration equipment (e.g., Terralift) [473], [474].

Trade Names. Hygropor, Styromull (BASF, Ludwigshafen, Germany); Styrofoam (Dow Chemical, Midland, Mich.).

7.1.2. *Primarily Open-Cell Urea – Formaldehyde Resin Foams*

Urea – formaldehyde foams consist of condensates of urea with formaldehyde in a well-defined molar ratio. They are solid foams with rigid walls and little flexibility. The materials used as soil conditioners are mainly urea – formaldehyde foams modified for plant compatibility.

Physical Properties. Urea – formaldehyde foams can be produced with densities of 2 – 50 kg/m^3 (as water-free uncomminuted material); foams with a density of 22 kg/m^3 are used for mixing into soils and substrates. Packed moist from processing, urea – formaldehyde flakes (trade name Hygromull) weigh approximately 35 – 40 kg/m^3.

The cell walls are partly open. They are thicker, and the cell volumes smaller, the higher the density. Cell diameters lie between 100 and 300 µm [460], [475], [476]. The capillarity is low (1 – 2.5 %); the capillary elevation is 300 – 400 mm [460]. The capillary elevation for a garden substrate treated with foam is described as advantageous [477].

The grades used as soil conditioners are made water-absorbing by modification of the condensate resin and comminution to flakes measuring 4 – 20 mm. Under vacuum, the water capacity is more than 90 vol % [478]; for Hygromull flakes having a density of 22 kg/m^3, this corresponds to 4100 wt %. The water capacity can be determined appropriately by the method of DIN 11542 (1967). At atmospheric pressure, the initial water uptake is slow but rewetting is very fast [478].

Water release is uniform and goes to completion without losses due to evaporation, so that the water stored in the foam flakes can be economically utilized by

plants. The water is held in place by suction forces of pF 1.2 – 2.54 (cf. Section Soil Water – Plant Relationships; see ⟶ Ceramics, General Survey, for definition of pF). Urea – formaldehyde foams in a loose bed have the permeability of moderately fine sand; under 25 – 35 % compression, that of fine sand [479].

Chemical Properties. As the condensation product of urea and formaldehyde, the foams are synthetic organic substances. Incorporated into moist soils and substrates in flake form, they are known to be biodegradable. At pH 6 – 7, the process goes at 3 – 5 % per year [480]; at pH 3.9 – 4.1, degradation is speeded up (15 – 20 %), especially at temperatures over 40 °C. The stability falls off rapidly above 80 °C. In horticultural substrates, steam sterilization is tolerated up to a maximum of 1 h.

The components of the urea – formaldehyde foams are readily biodegradable: The urea component mineralizes to ammonium and is then converted microbially to nitrate. The formaldehyde component is liberated upon mineralization; it undergoes microbial degradation in 48 – 72 h in soil or water, even more quickly in air. Bioaccumulation does not occur [481].

A theoretical effective lifetime of some 20 – 30 years is desirable for soil conditioning [462], [482].

Raw Materials and Manufacture. A process, part of which has been patented, is used to produce foams from modified urea – formaldehyde condensation products with compressed air, foaming agents, and hardeners in fixed or mobile equipment [483].

In Germany, the maximum allowable workplace concentration (MAK) in production is 1 ppm formaldehyde; this level may be exceeded only for short periods and within limits. In the United States, the absolute MAK is 3 ppm.

Use. The use of urea – formaldehyde foams as soil conditioners has been described by DOEHLER [484]. BAUMANN advanced their use (1953 – 1968) and developed the Plastopanik technique [459]. Foams were brought into reproducible use through extensive research [458], [460], [462], [470], [485], [486].

For reasons of cost, applications cluster in the areas of garden crops, such as pot and container plants, cut flowers (e.g., carnations, chrysanthemums), flower bulbs, fruits (including strawberries), vegetables, and eucalyptus, and in landscaping, where foams are used in newly seeded lawns and woods, in the transplanting of large trees, and in sports areas and golf courses.

In terms of soil physics, urea – formaldehyde foams optimize the air and water regimes in soils and substrates. They enhance the pore volumes, the maximum, minimum, and plant-available water capacity, and the aeration, and they lower the soil density. Plants respond with improved shoot and root growth, better early growth and development rates, and increased crop yields and qualities [462].

Trade Names. Hygromull, Hygropor (mixtures of Hygromull with Styromull) (BASF Aktiengesellschaft, Ludwigshafen); Agricon (Intrinco, Vaduz, Liechtenstein).

Official licenses have been issued for Hygromull and Hygropor in Austria, Belgium, France, Luxembourg, the Netherlands, Norway, Spain, and Switzerland and also for Agricon in Saudi Arabia and other Middle Eastern countries.

7.2. Colloidal Silicates

Colloidal silicates include compounds of polysilicic acid, produced and stabilized mainly by synthetic means, with a high content of reversibly soluble silicic acid and added flocculating electrolytes [460], [462], [487-489].

Agrosil colloidal silicate consists of (1) partly dehydrated sodium silicate, precipitated (neutralized) with acids, (2) electrolytes (phosphate, sulfate), and (3) an organic additive to retard aging. Official licenses have been issued for it in Austria, Belgium, Denmark, France, Luxembourg, the Netherlands, Norway, Spain, Sweden, Switzerland, and some Middle Eastern countries.

Physical and Chemical Properties. Colloidal silicates are solid, fine-grained, and thus easily distributed substances that can be dispersed with water to form silica gels and silica sols. Silica gels, examined under the electron microscope, are described as porous; they exhibit surface activity for the addition and inclusion of water and nutrients [490], [491]. Incorporated into soils, they fill the voids between soil particles [492] and bind these together with organic and inorganic complexing agents to form water-stable crumbs [462], [493-496]. Pore redistribution takes place in this process [490], [497]. Sorptive salt buffering has been described in soil mixtures [488], [491], [498].

The chemical activity is ascribed in particular to the low-molecular-mass silica sols. In the soil, they enable the holding of phosphate in solution or its activation by desorption [490]; depending on the pH, they can irreversibly fix heavy metals [461], [462], [499-504].

Raw Materials and Manufacture. Raw materials for the production of Agrosil colloidal silicate are spray-dried and liquid sodium silicate, phosphoric and sulfuric acids, and an organic aging retardant such as urea, humic substances, pectins, or proteins. The manufacturing process is patented [505], [506].

Use. Colloidal silicates are conceived as soil supplements or soil conditioners [462], [488], [493]. To a certain extent, they make it possible to return soils affected by salts and heavy metals to agricultural use [462].

Their action as soil conditioners depends on their incorporation in the soil and their ability to take up water (precipitation, irrigation). Quantities used per are (= 10^2 m^2) are 7 – 20 kg, preferably 10 – 15 kg. In gardening and landscaping, they have an effective lifetime of 3 – 5 years; aftereffects in unworked soils have been seen for 10 and 14 years.

Direct effects due to soil conditioning include improved water and sorption capacities, the activation of plant nutrients in the soil, physical improvement of soil structure through pore redistribution and crumb formation; and the fixing of heavy metals (such as Cd, Cu, Pb, and Zn) in the presence of alkaline earths. Indirect effects include improved soil life (respiratory activity and nodule bacteria), the release of excess water (a consequence of crumb formation), and enhanced phosphate mobility. The growth of new shoots and roots is encouraged, both organic and inorganic substances are accumulated in the vegetation in greater quantities, less water is needed, wilting of grass is reduced, and fungus and bacteria resistance is increased [462], [507].

In the Swiss classification, the product is not classed as toxic.

Trade Names. Agrosil (Guano-Werke AG, BASF).

7.3. Polymer Dispersions and Polymer Emulsions

Poly(vinyl acetate), poly(vinyl propionate), butadiene – styrene copolymer, *cis*-butadiene, and various acrylic acid polymers have been described and employed as soil conditioners with actions in and on the soil [460].

Physical and Chemical Properties. The products are mainly applied to the soil surface in aqueous solutions. They cross-link the particles of the uppermost soil layer and, depending on the concentration of the active agent, form a closed film or networklike coatings. These are permeable to precipitation but diminish evaporation. Incorporated into the soil, they promote crumb formation [494].

As organic substances with a relatively high dilution, polymer dispersions are degraded relatively quickly by UV radiation when on the surface of the soil and by microbial action when in the soil. Their action is therefore limited in time, and their stability depends on ambient conditions such as cold and heat.

Raw Materials. ⟶ Polyacrylamides and Poly(Acrylic Acids); ⟶ Polyacrylates; ⟶ Poly(Vinyl Esters); ⟶ Rubber, 3. Synthetic

Use. Polymer dispersions are employed chiefly for seed protection in landscaping, and also in vegetable and flower-bulb growing. They are applied at planting time by spraying, usually along with fertilizers and soil conditioners (e.g., Agrosil) or mulches (cellulose, straw). They can also be applied after planting by area spraying or, in the case of vegetables planted in rows, by stripe spraying [508].

The quantities used depend on the product and vary between 10 and 50 g/m^2 ; the dilution with water depends on the purpose and varies between 1 : 1 and

1 : 60 (product : water).

The duration of the structure-stabilizing or protective action depends on the quantity used [509] and on environmental conditions such as weathering and insolation.

Polyacrylates and polyacrylamides are recommended for use alone or with, e.g., starch to promote water storage in soils [460], [510-515]. The waterholding effect is, however, greatly diminished by pH values higher or lower than 7.0, water hardness, and dissolved substances such as urine or soil nutrients. No satisfactory practical solution has been found for these limitations [516], but more recent generations of these so called superabsorbers are claimed to be more tolerant towards dissolved salts. Various applications to gardening substrates and flower-growing soils have been described [517].

Polymer formulations are used for protection against erosion, especially in conjunction with the sprouting of seeds. They perform an environmental function by offering limited protection to the seeds or small plants against wind and rain erosion until the plants are large enough to protect themselves. They are of increasing importance in furrow irrigation systems in North America for preventing soil erosion and increasing water infiltration into the soil. A concentration of 10 ppm in the irrigation water is necessary to achieve the desired effects [518]. Biodegradability is a prerequisite for the soil and plant application of selected polymers. Biodegradability is not assured in the case of some polyacrylates.

Trade Names. Curasol for poly(vinyl acetate) (Hoechst Aktiengesellschaft, Frankfurt); Hüls 801 for *cis*-butadiene (Chemische Werke Hüls, Marl); Aqua-Gel for polyacrylate plus starch (Miller Chemical and Fertilizer Corp.); Hydrogel Viterra for poly(ethylene oxide) (Union Carbide Corp., New York); SGP Absorbent for sodium polyacrylate plus starch (General Mills Chemicals, Inc., Minneapolis, Minn.); Soiltex G1 for polyacrylamides (Allied Colloids).

7.4. Tensides

Many tensides have been tested as soil conditioners, including ammonium laureth sulfate, ethoxylated alkyl phenols, polyoxyethylene esters of alkylated phenols, polyoxyalkylene glycols and their polymers, polyoxyethylene, polypropoxypropanol glycol butylesters, alkyl polyglycosides, sulfosuccinates, and poly (propylene oxide)s. The hydrophobic ends of the molecules of the these so-called wetting agents are adsorbed by water-repellent organic matter, and the hydrophil ends link the soil particles with water.

Use. In turfgrass culture thatch accumulation may occur due to reduced decay of the organic matter of the grass sward. Under dry conditions, this material becomes hydrophobic, and irrigation results in water losses because of poor infiltration rates and run-off [519], [520]. Spraying of wetting agents onto the affected areas at a rate of 10 – 20 L/ha increases water absorption and efficiency. Solid formulations are also available.

Trade Names. Primer (Aquatrols, USA); wetx'tra (Rhône Poulenc, France); Turf Ex (Service Chemicals, UK), Saturaid (Debco, Australia).

[Top of Page]

8. Storage, Transportation, and Application

Karl-Heinz Ullrich and Hermann Mühlfeld

Fertilizers are produced continuously, year-round, in large capital-intensive plants, but they are sold only in a few months at the beginning of and during the vegetation period. Large quantities must therefore be stored for long times. The logistic of delivering the product to the user at the proper time leads to a subdivision of storage into plant storage, dealer storage, and user storage. In this way, loading and transport are spread evenly through the year, with additional control by seasonally varied sales rebates.

The construction and operation of storage facilities depend on the size, the location, the type of fertilizer, and the danger level, all of which are dictated by the product.

8.1. General Storage Requirements

Fertilizers are classified as follows by danger level:

- Group A. Explosive fertilizers, such as those with a high ammonium nitrate content or with a low ammonium nitrate content and > 0.4 wt % organic matter.
- Group B. Fertilizers in which self-sustaining, progressive thermal decomposition (low-temperature decomposition) is possible. In the past this group comprised mainly multinutrient fertilizers which contain ammonium nitrate. Today, the ammonium nitrate based multinutrient fertilizers which are marketed are almost exclusively rated Group C.
- Groups C and D. Fertilizers that do not explode and are not susceptible to self-sustaining, progressive thermal decomposition.

The precise classification is set forth by law [521]. With its technical regulations, the German regulation concerning hazardous substances (*Gefahrstoffverordnung*) prescribes in detail how to construct and to operate storage facilities for ammonium nitrate based fertilizers. How many regulations have to be observed depends on the classification of the fertilizer. The strictest standards apply for Group A, followed by Group B. For nonflammable fertilizers (Groups C and D), the normal storage conditions for bulk materials apply.

Most fertilizers come in granular form and readily absorb moisture. As a result, they experience caking or granule disintegration; either effect makes application more difficult. The storage areas must therefore be dry. Not only the roof and walls must be tight, but the floor must be safe against rising moisture. Care must also be taken that moisture does not get into the storage building because of too much air circulation. Doors and windows must be kept closed when the relative humidity is over 65 %. The surface : volume ratio in storage should be as small as possible.

Fertilizers containing ammonium nitrate, especially calcium ammonium nitrate, must be protected from direct sunlight and from repeated temperature changes at 32 °C, because otherwise repeated recrystallization leads to granule disintegration.

When ammonium nitrate fertilizers are heated above 130 °C, low-temperature decomposition sets in, generating gases that may be toxic, depending on concentration. Practices must therefore be employed that safely prevent the action of fire or external heating. Such practices include general fire-protection measures such as no smoking, no use of fire or open light, and no unauthorized entry. Ammonium nitrate fertilizers must not be mixed with flammable materials (sawdust, coal dust, sulfur, petroleum, etc.) or with acidic or basic substances (lime, basic slag phosphate, acid salts, etc.). Welding and burning work may be carried out only with the most stringent safety precautions. Electrical equipment must be located outside the fertilizer pile. Cables and wiring must be located at least 0.5 m above the highest possible pile level. Special care should be taken that the pile does not cover up lights, especially portable lights connected by cable to the power supply.

With regard to moving mechanical parts (belt, screw, and bucket conveyors, etc.), care must be taken that these devices cannot run hot or experience fertilizer buildup at critical points. Diesel and gasoline trucks that go directly into the storage area represent a danger due to hot exhaust gases and hot mufflers. Hardened fertilizers must be loosened mechanically, not with explosives.

Low-temperature decomposition can be detected by white or brown smoke or a piercing smell. If this process develops and is recognized promptly, the sintered reaction zone can be separated from the unreacted fertilizer. Good access is needed, and precautions are needed to keep the sizable amounts of gas evolved from being a health hazard. If safe access is not possible, the decomposition must be brought to a stop by cooling with water. If any low-temperature decomposition takes place, an alarm must immediately be sent to the fire-fighting service.

Fertilizers affect most of the conventional building materials, especially when wet. Steel, aluminum, and zinc suffer more rapid corrosion and must be protected by several coats of paint (total thickness > 180 µm). Fertilizer dust can cause brittle fracture at welds in steel. Subsequent welding must be carried out with special care.

Mineral fertilizers attack concrete more or less severely, causing scaling and corrosion of the steel reinforcement. For this reason, concrete floors contacted by fertilizer should be protected by filled coal-tar pitch or epoxy-based plastic.

Wood, especially in the new form of glued lamellae, is a suitable material. Care should be taken to use corrosion-resistant fasteners.

Plant Storage. Storage at the fertilizer plant is almost always in bulk form. Large warehouses, with capacities of up to and beyond 50 000 t for one or more grades, are employed. The total storage capacity is usually several months' production. The size, shape, and outfitting of the warehouses depend on the frequency of shipping, the number of grades, the required loading capacity, and the area available. In order to reduce the risk, some grades are limited as to amount stored in a single warehouse, which may be accomplished by dividing the building. Large quantities are stored in elevators (tower silos) only under some restrictions, because of the risk of caking and the resulting high reclaiming cost.

If enough space is available and shipments are not frequent, a flat-floor warehouse in which material can be piled more or less high against the walls is the most economical design. Trough-shaped or basin-shaped storage structures with appropriate reclaiming equipment are used when space is limited and intervals between shipments are short.

The material used for the foundation and walls is usually reinforced concrete; the roof is most often made of wood. Glued lamellar wood construction makes it possible to span wide buildings without posts. Fertilizer can be piled against the walls to a height of 10 m or more. However, if the pile is too high, the material can segregate during placement. Slides during reclaiming are also a problem if material is piled too deep. The plant warehouses generally need not be heated, since the fertilizer leaves the production facility at a temperature of 35 – 45 °C (not over 50 °C). On the other hand, overhead conveyors and loading apparatus spanning moderate distances should be heated to keep them dry.

Piling is done mainly with overhead belts at the center or side, with transverse distribution by belts, chutes, or discharge pipes. Newer facilities have a distribution control room with closed-circuit television units.

Reclaiming capacity must be several times piling capacity. Because requirements vary, several methods have been devised. For high capacity and short shipment intervals, track-borne scrapers capable of automation are used. Bridge cranes are also employed. Many wheeled tractor loaders are in service; these can be shifted from one location to another, easily replaced if damaged, and reinforced if necessary. All warehouse equipment moves material by way of transfer hoppers to conveyor belts, troughs, or bucket conveyors, which carry the material to the loading point. Crucial factors in the choice of equipment are the loading capacity required, the storage qualities of the fertilizer, the cost of structures and equipment, the safety of the operation, and the expected operating costs.

Warehouses are not usually operated on the first in, first out principle. For practical reasons, however, the warehouse should be emptied completely from time to time, since varying raw materials may result in slight color variations, while going to zero aids precise inventorying, and for other reasons.

Shipping from the Plant. Fertilizers at present are usually shipped in bulk, in self-discharging railroad cars, trucks, silo cars with pneumatic loading of elevators, and canal boats and barges.

Before shipping, many plants screen the fertilizer again to remove dust, lumps, and impurities.

Shipment of fertilizers in bags is declining. The product is usually put in 50-kg open bags (pillow bags), which are then sewed or welded shut, or in valve bags. Valve bags are better suited to stacking on pallets because of their boxlike shape. Most bags are made of plastic — extruded polyethylene tubing or woven polypropylene strips coated or lined with polyethylene. Paper and jute bags are now rarely used. The machinery industry has developed largely automated equipment for bagging and loading or palleting, and much work is still under way to improve these devices and adapt them to various requirements. Because of the associated high investment costs, bagging takes place mostly at the fertilizer plant. Palleting, which simplifies subsequent transfer of the bagged product, has gained in importance. In many countries, fertilizers are shipped in large 500 – 1000-kg bags, likewise made of woven polyethylene or polypropylene.

Dealer Storage. Fertilizer is stored chiefly in buildings, which are usually divided boxwise. Because of the caking tendency and the resulting problems with reclaiming, especially in the case of ammonium nitrate fertilizers, elevators find use only for free-flowing grades, for a limited span of time, and for quantities up to 30 t.

In building storage, special care should be taken to protect against moisture, since the fertilizer no longer has its heat from production, and it often sits for several months under cool, moist conditions. Before receiving material, the warehouse must be completely dry. Fertilizer should be placed continuously, without long breaks. The pile height should not exceed 5 m. Immediately after placement, the fertilizer surface must be carefully covered with film not less than 25 µm thick, because of the mechanical stress. Joints in the film must have an ample overlap, usually 1 m. A tight seal should be made at the walls (e.g., with wood lath). Air circulation should be minimized (closed windows and doors, airtight roof). If product is reclaimed in stages, the cover must be restored each time.

A belt conveyor is suitable for placement of fertilizer. Mechanical abrasion restricts the use of screw conveyors (not over 5 – 6 m, 100 rpm).

User Storage. The interim storage of mineral fertilizers by the consumer is declining to the same extent that the dealers become more willing to undertake this kind of storage. Bulk fertilizer is kept mainly in flat storage boxes, just as in the trade, and the boxes are similar to those used for dealer storage. Elevator storage is practiced on a very limited basis.

Bagged product can be stored by the user without major precautions. To simplify transfer operations, between 20 and 30 50-kg bags are assembled on a pallet, with or without shrink-wrap; in some countries, large bags (0.5 – 1.0 t) are also employed. Bagged fertilizer can be stored outdoors for a limited time under certain conditions (no temperatures over 32 °C, white UV-stabilized covers).

Transportation. Group B fertilizers can generally be transported without special precautions. Only in exceptional cases are they considered hazardous goods as defined in the transportation regulations. Specific provisions for Group B, as well as Group A fertilizers, are set forth in international regulations for various kinds of carriers. The most important rules are recognized by nearly every industrial nation and have been incorporated into the national regulations.

Sea transport: IMDG (International Maritime Dangerous Goods Code)
Rail transport: CIM (International Convention on the Transport of Merchandise by Rail)
Road: ADR (European agreement concerning the international transportation of dangerous goods by road)
Air: IATA-RAR (IATA Restricted Articles Regulations)

The CFR contains rules for all modes of transportation in the USA.

8.2. Application

Solid mineral fertilizers are generally applied to agricultural sites in the form of granules, coarse or fine crystals, and powders. Fine crystals and powders are becoming less and less important, with the exception of lime which is used almost exclusively in powdered form.

To achieve a good nutrient efficiency and to avoid environmental pollution, the equipment used for the application of mineral fertilizers has to meet the following requirements:

1. Exact calibration of the amount of fertilizer applied and uniform distribution, both in the direction of travel and in the transverse direction, and independent of traveling speed and application rate.
2. In order to attain a high area of application, the effective band must be wide and the distributor design must permit a high rate of operation. The rate must be variable between 50 and 1000 kg/ha. Special distributors for liming must offer rates of up to 5000 kg/ha.

The uniformity of fertilizer application can be determined exactly on a test stand. Boxes with areas of 0.25 m^2 catch the fertilizer over the whole application width, and the product is then weighed. The mean is calculated from the individual values. The smaller the mean deviation from the average value, the more uniform the fertilizer distribution. Internationally, the test method is largely unified, so that the results are also easily comparable from country to country.

Application Equipment. Mineral fertilizers in the form of granules or coarse crystals are generally applied by broadcasting-type fertilizer distributors. Spreader rigs with pneumatic transverse distribution are also utilized, but their use is of declining importance. Powdered fertilizers such as lime are preferably applied by fixed-width fertilizer spreaders with mechanical transverse distribution to avoid dust formation during operation.

Broadcasting fertilizer spreaders, also called spinner spreaders, operate with working widths of 6 – 36 m. They are characterized by simple construction and easy handling, together with a high area performance. They constitute the absolute majority of all fertilizer distributors. Broadcasting fertilizer spreaders distribute the fertilizer over a semicircular to semi-elliptical area around the spreading device. The spreading width is greater than the effective working width. As the amount of fertilizer which is applied per unit area decreases towards the borders of the spreading swath, overlapping of adjacent swaths is necessary for uniform transverse distribution of the fertilizer (Fig. 36). Modern broadcasting spreaders have broadcasting patterns with extremely flat sides, so that the risk of distribution errors in the overlap zone is minimized.

Figure 36. Broadcasting pattern for spinner spreaders

Three types of broadcasting spreaders with different spreading devices exist: single-disk, twin-disk, and oscillating spout (pendulum) spreaders (Fig. 37). The twin-disk spreader is gaining importance over the single-disk and oscillating-spout spreaders, since its basic concept is better suited for further technical development. Consequently, the spreading quality of twin-disk spreaders has been raised to a level almost matching that of pneumatic spreaders.

Figure 37. Broadcasting spreaders: single-disk centrifugal distributor (A), twin-disk centrifugal distributors with side-by-side (B) and over-and-under spinners (C), oscillating-spout distributor (D)

The spreading device in oscillating-spout spreaders is a pendulum tube that moves to and fro. Since this spreading technique allows working widths of only 6 – 15 m, whereas the large fields of modern agriculture require increasingly greater swath widths, the importance of oscillating spout spreaders is also diminishing.

Fixed-Width Fertilizer Spreaders. With fixed-width spreaders the transverse distribution of the fertilizer is achieved by means of booms, either pneumatically or mechanically. Unlike spinner spreaders, only one working width is possible.

In pneumatic fertilizer spreaders, the fertilizer is metered at the hopper by cam wheels, fed into distributor tubes, and transported by blast air to discharge outlets along the spreader booms, which are provided with deflectors (Fig. 38). Depending on the boom length, working widths of up to 24 m are possible. When working with a pneumatic spreader, overlapping of adjacent swaths is required, as with a spinner spreader. However, due to the steep flanks of the broadcasting pattern, the required overlap is much smaller (Fig. 39). Pneumatic spreaders can be used for the application of granulated and crystalline mineral fertilizers, if possible free of dust.

Figure 38. Schematic of a pneumatic fertilizer spreader

Figure 39. Broadcasting pattern for pneumatic spreaders

Spreaders with mechanical transverse distribution are generally equipped with a screw or auger (auger-type spreaders) Fertilizer flowing from the hopper is conveyed to the driven auger by various means and is then transported to the spreader tubes with adjustable discharge spouts (Fig. 40). Depending on the boom length, working widths of 6 – 8 m are possible. Auger-type spreaders are preferably used for the application of powdered fertilizers. Boom length and working width are identical. For uniform fertilizer distribution, exact driving in parallel runs is indispensable (Fig. 41).

Figure 41. Broadcasting pattern of a spreader with mechanical transverse distribution

Electronically Controlled Spreading Equipment. Electronic control units are increasingly being used to monitor and to improve the metering and distribution of mineral fertilizers. Thus, the correct amount of fertilizer can be automatically discharged when the traveling speed of the spreader is changed, and the amount of applied fertilizer can be displayed, based on permanent monitoring of the fertilizer discharge.

Site-Specific Fertilizer Application Guided by GPS. Until now farmers' fields generally received a uniform fertilizer rate. With the steadily increasing size of individual fields this practice is bound to change, as increasing field size also implies increasing heterogeneity of the soil and thus of the crop yield. For economical and environmental reasons, a future development towards the site-specific management of large-sized fields is imminent. Under this aspect, the global positioning system (GPS) is currently being tested under practical conditions for its suitability for crop management, including fertilizer application. GPS allows the exact position in the field to be determined and relocated, regardless of weather, location, and time. On this basis, it should be possible to apply fertilizers site-specifically in accordance with the existing soil and crop variations within a field. The complete technology, from yield recording by the harvester to nutrient application with the fertilizer spreader, has yet to be further developed. This will probably take another 5 to 10 years.

[Top of Page]

9. Environmental Aspects of Fertilizer Application

Wilfried Werner

Fertilizers are used to enhance soil productivity or fertility (amelioration fertilization) or to maintain it at an economically and ecologically acceptable level (maintenance fertilization). The task of fertilizers is to replace the nutrients lost through the harvest and by other causes: irreversible fixation in the soil,

leaching, escape in gas form, etc. Along with the positive effect of fertilizer application, there are also negative effects, especially with improper use.

Up to the beginning and middle of the 1970s, environmental problems triggered by fertilization practices were subject to local discussion only; examples were the buildup of heavy metals in soils and crops when sewage sludge was applied, the buildup of nitrates in the groundwater where vegetables were raised in the catchment areas, and the eutrophication of surface waters due to phosphates. Only later was the partly regional character of local environmental problems acknowledged.

From the early 1990s onwards, increasing emphasis was also placed on global aspects of the impact of fertilization on the environment, i.e., the influence of agricultural production in general and fertilization in particular on the increased emission of greenhouse gases. The awareness of the mutual relationship between surplus production of agricultural products and environmental problems within the EU has continuously grown over recent decades. In particular the interest in mineral emissions from agriculture has increased substantially, both in policy making and research and in practical farming.

9.1. Nitrogen

Of all plant nutrients, nitrogen is the most effective in economic terms, but in ecological terms the most problematic. The plant absorbs nitrogen mainly as nitrate (NO_3^-) but partly as ammonium $\left(NH_4^+\right)$. The plant's ability to assimilate larger molecules with organically bound nitrogen is limited.

Problems with nitrogen arise from a local or regional excess of nitrogen, regardless of its origin. Several cases, which are mostly of a regional character, are described first, then solutions are listed. Figure 42 summarizes the environmental aspects of nitrogen.

Figure 42. Agricultural nitrogen as an environmental factor

9.1.1. *Ground Water*

Various sectors of the economy — agriculture, forestry, water resources and wastewater management, transport, energy, and industry — are involved in ground water and surface water problems having to do with nitrogen. With regard to ground water, the quality of drinking water is the prime concern. A reduction in the maximum allowable nitrate content in drinking water within the EU, from 90 mg/L to 50 mg/L, has made the nitrogen problem more acute.

Until 1970 – 1975, virtually the only negative aspects considered with respect to nitrate were methemoglobinemia and the nitrate – nitrite – nitrosamine problem. Later, a number of other reactions triggered by nitrate and sulfate in the aquifer or during transport to it have come under discussion. Depending on the presence of aerobic or anaerobic conditions, the intensity of NO_3^- (and SO_4^{2-}) application, and the reserves of microbially available carbon sources, the reactions listed in Table 34 can yield the following compounds:

HCO_3^- or $Ca(HCO_3)_2$	water hardness
N_2O	stratospheric ozone break-down
NH_4^+;	undesirable, toxic, or
H_2S;	foul-smelling
Fe^{2+}, Mn^{2+}	
$Fe(OH)_3$	ferric incrustation of wells

If available carbon sources are not present, or exhausted, nitrate (or sulfate) can break through into the ground water.

From around 1980 up to now increasing emphasis was placed on ground water as prime source of diffuse nitrogen pollution of surface waters [525], [526].

Table 34. Sequence of environmental problems in the presence of excessive nitrate and sulfate in the pedosphere and hydrosphere

Oxygen and glucose in soil and ground water	Reduction processes	Energy released per mole of glucose, kJ	Problematic parameter: Input	Problematic parameter: Output *
Decreasing O_2 supply; Decreasing supply of available organic carbon	*Catabolic reduction of O_2, NO_3^-, and SO_4^{2-}*			
	Respiration			
	$C_6H_{12}O_6 + 6O_2 \longrightarrow 6CO_2 + 6H_2O$	2876		
	Denitrification			
	$5C_6H_{12}O_6 + 24NO_3^- + 24H^+ \longrightarrow 30CO_2 + 42H_2O + 12N_2$	2712		
	$C_6H_{12}O_6 + 6NO_3^- + 6H^+ \longrightarrow 6CO_2 + 9H_2O + 3N_2O$	2578	NO_3^-	N_2O
	Nitrate respiration			
	$C_6H_{12}O_6 + 12NO_3^- \longrightarrow 6CO_2 + 6H_2O + 12NO_2^-$, $NO_2^- \xrightarrow{H^+} NO_x$	1946	NO_3^-	NO_x
	Ammonification			
	$C_6H_{12}O_6 + 3NO_3^- + 6H^+ \longrightarrow 6CO_2 + 3H_2O + 3NH_4^+$	1817	NO_3^-	NH_4^+
	Sulfate respiration (in the absence of NO_3^-)			
	$C_6H_{12}O_6 + 3SO_4^{2-} + 6H^+ \longrightarrow 6CO_2 + 6H_2O + 3H_2S$	486	SO_4^{2-}	H_2S
Supply of available organic carbon exhausted	*Inorganic reduction of NO_3^-*			
	Dentrification with pyrite			
	$5FeS_2 + 14NO_3^- + 4H^+ \longrightarrow 7N_2 + 10SO_4^{2-} + 5Fe^{2+} + 2H_2O$		NO_3^-	SO_4^{2-}, Fe^{2+}
	Dentrification with soluble iron			
	$10Fe^{2+} + 2NO_3^- + 24H_2O \longrightarrow N_2 + 10Fe(OH)_3 + 18H^+ + N_2$		NO_3^-	$Fe(OH)_3$
	Dentrification with elemental or organic sulfur			
	$5S + 6NO_3^- + 4H^+ \longrightarrow 3N_2 + 5SO_4^{2-} + 4CO_2 + 2H_2O$		NO_3^-	SO_4^{2-}

* Any reaction producing CO_2 is able to increase the concentration of $CaHCO_3$.

Causes of Nitrate (and Sulfate) Damage. The following cases have been described in the Federal Republic of Germany:

1. Ground water lowering, plowing of pastureland, intensive cropping with N fertilization [527]
2. Intensive cropping with vegetables and/or intensive stockbreeding with appropriate N fertilization (Fig. 44) [528-532]
3. Intensive agricultural land use — commercial gardening, animal husbandry — with appropriate N fertilization [533]
4. Commercial gardening, intensive white asparagus cultivation, overuse of mineral fertilizers (Fig. 45) [534], [535]
5. In the Netherlands, the ground water in regions with intensive stockbreeding (the provinces of Geldern and Brabant) displays not only elevated nitrate levels but often high ammonium values at depths between 10 and 25 m [536]

Recent surveys on the nitrate concentration of the ground water in Germany resulted in quite different frequency distributions for a representative overall set of measurement points and a special set of measurement points restricted to agricultural “loading areas” according to EU Directive 91/676. In the representative survey, only 10 % of the samples exceeded the EU threshold concentration for drinking water, whereas in the near-surface groundwater of so-called agricultural-loading areas this was the case in more than 60 % of the samples (Fig. 43).

Figure 43. Frequency distribution of NO_3^- concentration in ground water in Germany [537], [538]

Figure 44. Nitrate and sulfate in the raw drinking water of Mussum, North Rhine-Westphalia, Federal Republic of Germany, 1910 – 1996 [532], [539].

Figure 45. Nitrate concentration in water from three wells of Bruchsal Waterworks, 1973 – 1983 [540]

The insert shows the location of wells no. I – III.

A distinction should be made between acute and chronic nitrate problems. Extreme overfertilization or pastureland plowing can cause sudden, acute nitrate damage in soils threatened by leaching (sandy soils, high water table, low or declining denitrification capacity). For example, years of overapplication of N (mainly for asparagus, with more then ten times the N depletion by the crop) in the drinking-water catchment area of the Bruchsal (Federal Republic of Germany) waterworks overloaded the denitrification capacity and caused a jump in nitrate in well waters (Table 35, Fig. 45) [535], [540].

Table 35. Denitrification potential and nitrate nitrogen concentration 2 – 3 m and 3 – 4 m under the surface of forest (pine or alder) and farmed land (cereals or asparagus) at Bruchsal (Federal Republic of Germany) in February, 1986

	Forest near well number I		Intensively cropped land near well number III	
	Pine	Alder	Cereals	Asparagus
2 – 3 m under the surface				

Denitrification potential *, kg/ha	427	583	67	21
Nitrate nitrogen, kg/ha	6	18	23	56
3 – 4 m under the surface				
Denitrification potential *, kg/ha	238	258	50	17
Nitrate nitrogen, kg/ha	4	3	50	60

* The denitrification potential is the concentration of water-soluble carbon, as glucose, multiplied by 10/27, which corresponds to the stoichiometry 5 $C_6H_{12}O_6$ + 24 NO_3^- (see Table 34).

Over a long period, an acute nitrate problem may become chronic. Even under economically optimal fertilization matched to base outputs, elevated ground water nitrate levels can come about [535], [541], [542]. The base outputs arise through leaching of water-soluble nitrogen-bearing substances. The unavoidable nitrogen base outputs, primarily in winter, are between 20 and 40 kg ha^{-1} a^{-1} [543-545]. A chronic nitrate problem is much more severe than an acute one with respect to detection and propagation, as well as the cost and the success of rehabilitation measures.

The causes of damage can be classified as follows:

1. Plowing of pastureland, forced in part by prior ground water lowering. In three to four years, this process robs light soils of 6 – 7 t of organic nitrogen through mineralization and leaching out of the root zone [546], [547]. In heavy soils, the process takes much longer. The nitrate formed by mineralization is first denitrified by microorganisms, with the simultaneous degradation of the microbially available carbohydrates. The denitrification of 6 – 7 t of nitrate N requires 16 – 19 t of such carbohydrates. In this way, the available organic matter soon becomes the limiting factor, and the denitrification capacity of the soil is exhausted. In soils with shallow foundation, there is thus a danger that the N output of a nearby intensive farming operation will appear almost quantitatively in the ground water. Depending on how close the wells are, the raw water may show elevated nitrate levels for decades [548].
2. Inappropriate crop rotation. Examples of poor crop rotation include high fractions of fallow or semifallow land (e.g., corn [maize] or sunflowers), summer grains without or with inadequate (winter) intercrops, and large fractions of legumes, especially if they are plowed in too soon [545], [549]. These practices usually result in high leaching losses, chiefly in winter.
3. Corn rotation with excessive liquid manure. In regions of large-scale stockbreeding, for example, in parts of the Netherlands, Belgium, Germany, and France, excessive amounts of liquid manure were formerly — and in many forms are still — applied.
4. Incorrect nitrogen fertilization. The problem is usually excessive fertilization, poor timing, and unsuitable fertilizer form, usually not an inappropriate application method.

The danger of overfertilization with mineral fertilizers is especially great in commercial gardening and in single crops with low N depletion (orchards, vineyards). Vegetables are usually harvested in the principal growth period of the vegetative phase. Leafy vegetables, above all, offer good market quality only if a good nitrogen supply is available at the time of harvesting. Thus high residual levels of readily soluble nitrogen remain in the soil. Here again, it often happens that too much fertilizer is applied. The same holds for vinegrowing, especially over permeable limestone. In sugar beet farming, fertilizer nitrogen was formerly applied far in excess of the depletion. However, from 1980 until 1994 there was already a continuous decrease from 250 to 125 kg N per hectare in German sugar beet growing, on average [550].

In general, the danger of overapplication is less for mineral fertilizers than for organic fertilizers, since the nitrogen content in the mineral fertilizer, unlike that in manure, is known and constant. What is more, the mineral fertilizer can be applied more precisely with respect to both quantity and schedule. Finally, cost is an important factor in determining the rate of mineral fertilization.

Overapplication of organic fertilizers is a problem chiefly in heavily stock-oriented farming with liquid manure fertilization and in pasturage with grazing. Despite overapplication of organic fertilizers by a factor of one or two, compared to the residual nitrogen loss, mineral fertilizer N is often supplied in addition to improve yields. This is demonstrated by the total nitrogen balances of different farming types in Germany. The mean nitrogen surpluses were estimated for the financial year 1995/96 at 19 kg N per hectare for arable farms, 107 kg N per hectare for cattle farms, and 166 kg N per hectare for special pig and poultry farms [551].

9.1.2. *Surface Waters*

In common with the groundwater situation, many Western European rivers have shown a strong tendency towards increasing levels of dissolved nitrogen. As an example, in the period between 1954 and 1995 the nitrogen load, mainly as nitrate, from diffuse sources of the Rhine at the Lobith control station increased from 95 000 to 185 000 t N per hectare per annum [552].

The present share of diffuse sources in the total nitrogen input into surface waters in Germany is estimated at about 60 % [526], [553], [554], because the N input from point sources was drastically reduced since the mid-1980s due to the introduction of nitrification and denitrification treatments in sewage plants. Of the diffuse sources, the pathway via groundwater is highly dominant, accounting for roughly two-thirds. Drain water was responsible for an average input share of about 10 % of the diffuse nitrogen pollution of surface water in Germany. Hence, about three-quarters of total diffuse nitrogen input was due to leaching of nitrogen from upper soil layers, and nitrogen fertilization with both mineral and farm-produced fertilizers has an important impact on the level of leaching losses.

In connection with the nitrate N (and phosphorus) loading of rivers and wetlands, special attention should be paid to the drainage system in the agricultural area of the northern European lowland plains, with their intensive stockbreeding and liquid manure disposal. The danger of eutrophication not only by increasing phosphate inputs but also by rising nitrogen inputs into estuaries, coastal zones, and especially the tidal mud flats of the North and Baltic Sea coasts has come under discussion [555-557]. Sediments in these areas since about 1950 – 1960 display increasing contents of both P and N [558], [559].

9.1.3. *Atmosphere*

Agriculture is one source of problematic N compounds in the atmosphere: N_2O from nitrification and denitrification processes in the soil and, chiefly in stockbreeding areas, ammonia (Fig. 42).

N_2O Emissions. N_2O [10024-97-2], with an atmospheric residence time of 100 – 200 years, serves as a source of NO [10102-43-9]. In the upper stratosphere NO, along with HO radicals and halogenated hydrocarbons, contributes to the breakdown of ozone, which is associated with the danger of increased short-wavelength radiation on the earth and a correspondingly increased susceptibility to skin cancer in humans [560].

$$\begin{array}{l} O_3 \xrightarrow{h\nu} O + O_2 \\ O + N_2O \longrightarrow 2NO \\ 2NO + 2O_3 \longrightarrow 2NO_2 + 2O_2 \\ \hline 3O_3 + N_2O \longrightarrow 3O_2 + 2NO_2 \end{array}$$

Soil management is the most important agricultural N_2O source [561]; denitrification and nitrification are the responsible microbial processes [562], [563]. Intensive studies on N_2O emissions from agricultural soils carried out from the beginning of the 1990s gave average emission rates of 2 – 5 kg N_2O per hectare per annum for temporate zones [564], [565], [566], but much higher for tropical soils [567].

The total N_2O emission in Germany in 1990 was estimated by the Federal Environment Agency (UBA) at 143 × 10^3 t N per annum, with an agricultural contribution of 34 % [553].

The quantity of N_2O emitted from soils is determined by the content of available nitrogen, that is, by the level of N fertilization. Nitrogen fertilization was

responsible for 50 – 80 % of the emissions, and between 1 and 3 % of the fertilized N was lost as N_2O [568-571].

A worldwide estimate of direct and indirect emissions of N_2O from nitrogen fertilization and nitrogen fixation is given in Table 36. The direct emissions of N_2O are estimated at 1.25 ± 1 % of the applied N. The indirect emissions are ascribed to N from past years' fertilization, crop residues, from subsurface aquifers, and from recent atmospheric depositions [571]. An additional 0.75 % of the applied N will eventually be evolved from these indirect sources [572]. With increasing nitrate levels in the soil, the denitrification ratio N_2O/N_2 shifts in favor of N_2O [573]. The average share of N_2O in the total denitrification loss was assessed at 8.5 % [574].

Table 36. Estimates of direct and indirect global emissions of N_2O from application of fertilizer N (synthetic or animal waste) to agricultural soils and from soils growing biological N-fixing crops (10^6 t/a N_2O N) [577]

Region	Mineral N	Animal waste N	fixation	Total	Range
Africa	0.04	0.21	0.05	0.30	0.15 – 0.45
North and Central America	0.26	0.11	0.11	0.48	0.24 – 0.72
South America	0.03	0.22	0.09	0.34	0.17 – 0.51
Asia	0.75	0.52	0.19	1.46	0.73 – 2.19
Europe	0.27	0.22	0.02	0.51	0.26 – 0.77
Oceania	0.01	0.03	0.01	0.05	0.03 – 0.08
Former Soviet Union	0.17	0.18	0.03	0.30	0.19 – 0.57
Total	1.53	1.49	0.50	3.50	1.80 – 5.30

Ammonium-based fertilizers lead to higher N_2O emissions than nitrate-based fertilizers [569], [575]. Farm manures generally produce higher N_2O emissions, mainly due to the simultaneous application of quickly decomposable organic matter [576].

N_2O emissions due to N fertilization are mitigated by all measures to improve the efficiency of N use. The mitigation potential is estimated at up to 20 % [577].

NO_x ($NO + NO_2$) Emissions. NO_x, which has an average atmospheric residence time of 1.5 d, contributes to ozone synthesis in the troposphere:

$$NO_2 + O_2 \xrightarrow{h\nu} NO + O_3$$

The reverse reaction does not take place in the presence of carbon monoxide or reactive hydrocarbons, including methane, which is produced mainly by ruminants. Ozone can combine with unsaturated hydrocarbons from automobile exhausts to form ozonides, which react with NO_2 to yield peroxyalkyl nitrates

Ozone and the peroxy compounds are strong oxidizing agents with high phytotoxicity. They have been blamed for damage to vegetation in both forestry and agriculture.

The volume of NO_x emissions due to fertilization (from N reactions in the soil, nitrification more than denitrification [578]) and of plant NO_x emissions [579-581] is hard to assess. The contribution of agriculture to global NO_x emissions was estimated at 22 % (ca. 11 Tg NO_x N per annum), which consists of biomass burning (14 %) and the influence of mineral fertilization and manuring (each ca. 4 %) [582]. When the photooxidation of emitted NH_3 in the troposphere is taken into account, the figure rises to 27 %. However, NO_x is reabsorbed and metabolized by the plant, so that gross and net processes must be differentiated [583-587].

NH_3 Emissions. Ammonia emitted into the atmosphere reacts fairly rapidly (residence time < 9 d) to NH_4^+ and, after reaction with, say, SO_4^{2-}, is precipitated as ammonium sulfate, $(NH_4)_2SO_4$. Atmospheric NH_3 or NH_4^+ promotes the long distance transport of SO_2 or SO_4^{2-}. Ammonia and ammonium nitrogen forms do have fertilizing action, but in Western Europe the negative effects outweigh the beneficial ones in close-to-natural (forests, heath) and natural ecosystems (nature preserves, surface waters). Aside from the phytotoxic action of NH_3 in the area close to the emission source, deposition of NH_4^+ causes long-range damage:

1. Leaching of nutrients (e.g., K^+, Ca^{2+}, Mg^{2+}) out of the phyllosphere (leaves, needles) and the pedosphere (soil) followed by acidulation of the soil and waters [588-592]
2. Buildup of nitrogen in the pedosphere and nutrient imbalances in vegetation [589]
3. Injuries to mycorrhizae, the roots in symbiotic association with fungi [593]
4. Changes in the flora and fauna of terrestrial and aquatic ecosystems due to the promotion of nitrophilic species and the inhibition of nitrophobic species [589], [594]
5. Increased loss of N with leach water, especially in damaged coniferous forests [595-597]
6. Increased N inputs to surface waters [598], corresponding N buildups in marine sediments, especially in the North Sea and Baltic Sea coastal regions [558], [559]

Around the turn of the century (in remote regions even today) the mean annual depositions of atmospheric NO_3 N and NH_4^+ N were each ca. 1.3 kg/ha. Today, 10 – 15 kg/ha are deposited for each nitrogen form. On the basis of the filter capacity of the forest, the atmospheric N inputs may be increased by a factor of 1.2 – 2.0 (deciduous forest) or 3.0 (coniferous forest). In addition, a coniferous forest has a specific filtration capacity for NH_4^+ N but not for NH_3^- N [596], [599].

Recent measurements of the atmospheric nitrogen deposition into the soil – plant system with a new integral measurement system for wet, dry, and gaseous depositions even show annual net depositions of between 65 and 73 kg N per hectare at two locations in central Germany [600]. Clearly the earlier standard measurements underestimated the true magnitude of nitrogen deposition. Such nitrogen depositions exert a high pressure on natural or close-to-natural ecosystems because they greatly exceed the critical loads of these ecosystems.

The estimate of NH_3 emissions by agriculture is based on statistical figures of animal husbandry and fertilizer production and application, which all are multiplied by source-specific emission coefficients. Because of the different values of these specific coefficients given in the literature, all estimates of NH_3 emissions have a high range of uncertainty. An estimate for Germany (1992) resulted in the range from about 350 to 840 with a mean value of 577 Gg NH_3 N [601]. There are very large differences in the emission densities between and even within the federal states.

The estimates for Western Europe from different authors are in the range of 3.1 – 4.0 Tg/a NH_3 N [602]. As an example, Table 37 contains estimates of the anthropogenic NH_3 emissions from agriculture, industry, and other sources for 16 European countries. 90 % of the total emissions are due to agricultural activities, 74 % alone originates from animal husbandry (stabling, grazing, application of manure), and 12 % is attributed to the use of mineral fertilizers. The

total emission is 4.0 Tg/a NH_3 N ± 30 %, that is, 2.2 – 5.2 Tg/a NH_3 N.

Worldwide, including natural emissions, mineral fertilizers account for 2 – 5 % and stockbreeding 12.5 % of the total emissions of about 120 Tg/a NH_3 N [560]. The high proportion due to stockbreeding in Western Europe is accounted for by the high population density of animals and by the changeover from solid manure to slurry manure, which is less laborious but higher in NH_3 emissions. In comparison with stockbreeding, NH_3 emissions are lower even when solid mineral fertilizers high in NH_4 or amide N (ammonium sulfate, diammonium phosphate, urea) are used. This is especially true for soils where the pH and the free lime content are high or where directly incorporating the fertilizer into the soil is not possible. Liquid fertilizers with NH_4^+, because they infiltrate the soil, emit less NH_3 than solid NH_4^+ fertilizers.

Based on the specific NH_3 emission coefficients of the various N fertilizers and their application, NH_3 emission rates from mineral fertilizers in Germany are calculated by different authors to be from 2.1 to 8.1 kg per hectare per annum NH_3 N [603].

Table 37. Anthropogenic ammonia emissions from 16 European countries [602]

Country	Animal husbandry	Mineral fertilizers	Cultivated plants	Industry	Other sources	Total

Apart from the impact of nitrogen fertilization on greenhouse gases, there is growing concern about its influence on the sink capacity of soils for methane, the most important greenhouse gas after CO_2. Oxidation by methanotropic bacteria in the soil is the only biological sink for methane. An adverse effect of N fertilization on methane oxidation was first reported in 1989 [604]. Later it was found that ammonium strongly inhibits methane oxidation, whereas nitrate has only a minor effect if at all [605-607]. This is due to the competition between NH_4^+ and CH_4 for the enzyme methane monooxygenase [608].

9.1.4. *Biosphere*

Nitrogen fertilizer may produce undesirable N forms in the crop and changes in the composition of flora and fauna in nearby close-to-natural or natural ecosystems.

Undesirable N Forms in Crop. Because of the potential formation of nitrosamines, crops should not contain too much nitrate. However, the nitrosation of substances such as vitamin C [50-81-7] and α-tocopherol [59-02-9] suppresses nitrosamine formation.

Fertilization with nitrogen alone increases the content of stored N forms (such as NO_3^- N, basic amino acids, amines, and amides, and lowers the content of vitamin C in vegetative plant parts. This is more true for NH_4^+ fertilization than for NO_3^- fertilization. The content of α-tocopherol is virtually unaffected [609]. A balanced NPK application, on the other hand, can raise the vitamin C content [610], [611]. This is important above all to vegetable farming, especially with regard to the NO_3^- content arising from fertilizer, since the nitrate intake of human beings is derived about 70 % from vegetables consumed if the NO_3^- content in drinking water is low (<10 mg/L). As a result, countries in Western Europe have adopted guidelines or maximum levels for nitrate in vegetables. Limits are imposed, for example, in the Netherlands, Austria, and Switzerland. The Federal Republic of Germany has established guidelines, e.g., for fresh lettuce and spinach, 3000 and 2000 mg/kg, respectively.

Biodiversity. The diversity of both faunal and floral communities is influenced by agriculture and fertilizer use. On a site-specific local scale, fertilizer use in general and nitrogen fertilization in particular promote the growth of crops more than that of accompanying flora. In grassland, heavy use of nitrogen inhibits the growth of many herbs and legumes.

High amounts of fertilizer salts or anhydrous ammonia may have adverse effects on earthworm population by direct contact. However, the detrimental effect on the total population is very low. The greater supply of fresh organic material that becomes available when soils are raised low to high fertility by fertilization has positive effects on both earthworms and soil microorganisms.

On a global scale the use of fertilizers has positive effects on biodiversity in reducing population pressure for cultivating unsuitable fragile soils, felling of rainforests, and overgrazing, that is, by reducing or preventing soil erosion and degradation.

9.1.5. *Pedosphere (Soil)*

Nitrogen in cultivated soil (root zone, 0 – 120 cm) is an asset for agriculture, because nitrogen reserves and availability in this region are an important criterion for soil fertility. However, in close-to-natural or largely natural ecosystems, atmospheric N inputs in the forest, heath, nature preserves, lakes, and rivers can lead, over a long period, to a buildup of nitrogen in the soils; the harmless removal of this N (possible only through denitrification) is of concern to ecologists.

9.1.6. *Countermeasures*

Measures aimed at preventing or overcoming nitrogen problems due to N fertilization in all environmental zones can be divided into direct measures and indirect measures. The aim of both is to minimize the residual nitrogen in the root zone at the end of the vegetation period and hence the leaching potential.

Direct Measures in Fertilization. For arable crops such as sugar beet [550], significant progress has been made in reducing the fertilizer-related nitrogen leaching potential. To provide an economically and an ecologically accurate nitrogen recommendation, the nitrogen supply from soil reserves is assessed by methods such as electroultrafiltration (EUF) or, if not measurable, by empirical estimation. Nitrogen fertilizer is added only to account for the difference between the demand of the crop and the supply from the soil. The guideline for the plant N demand over time is the nitrogen depletion with the harvest. Because of inevitable N losses (denitrification, leaching, etc.), roughly 20 – 30 % extra nitrogen must be supplied over and above the depletion. Optimal distributing systems apply the fertilizer uniformly. Most farmers follow these principles.

The only way to accurately find the actual nitrogen demand is a nitrogen balance for a single farm or field. The ecologically acceptable N level may be higher than, equal to, or lower than the optimal fertilization level: this fact represents a potential incompatibility between economics and ecology. It is very important in this concern, that the new German “Fertilizer Utilization Decree” contains a commitment of farmers to bookkeeping, thus calculating the balances of mineral nutrients at form level.

Farm-Produced Fertilizers. The most urgent nitrogen problem in Western Europe is that the livestock population in large regions has long been above acceptable levels. To comply with clean-air and clean-water requirements, the former liquid manure regulations of some states in Germany, that still permitted using liquid manure of three live-animal units per hectare of agricultural land, an amount still far beyond what is economically beneficial and compatible with the environment, were replaced in 1996 by a federal Fertilizer Utilization Decree with some special requirements for the application of farm-produced manures, including the following:

- Limiting gaseous NH_3 losses by appropriate technical measures, consideration of weather conditions, and the incorporation of liquid manure into unplanted soils immediately after application.
- Using liquid manure in autumn after the harvest of main crops only for subsequent catch or in combination with straw incorporation and only in limited amounts (equivalent to 40 kg of NH_4 N or 80 kg of total N per hectare).
- No liquid manure application in winter from November 15 to January 15.
- Limitation of farm manure application to 170 and 210 kg N per hectare per annum on arable land and grassland, respectively, including nitrogen in animal droppings on pastures. Up to 20 % of total N in manure may be subtracted to compensate unavoidable NH_3 losses during spreading.

Mineral Fertilizers. The matching of N fertilizer application to economic and ecological requirements is much easier with mineral fertilizers than with farm fertilizers, since the mineral products — in contrast to the farm-produced ones — are defined within narrow limits as to N content, N form, and availability.

The nitrogen form is of secondary importance, since NH_4^+ and amide N are usually converted in a few days, perhaps 1 – 2 weeks, to nitrate nitrogen in agricultural soils. Nitrification inhibitors, added to NH_4^+ fertilizers to retard the conversion of NH_4^+ toNO_3^-, may afford an extra measure of safety where there is no acute ground water nitrate problem; however, they are only a partial solution to the problem [612]. (Nitrification inhibitors may promote the liberation of NH_3 from NH_4^+ fertilizers, especially when the fertilizers are not incorporated in the soil [613].)

Controlled-release forms of N may represent an improvement from the ecological point of view when they make it possible to satisfy the crop N demand over time better than can be done with conventional nitrogen fertilizers, and when no substantial amount of nitrogen remains in the soil after the vegetation period.

Indirect Measures. All practices that lead to gains in yield without additional N alleviate environmental nitrogen problems due to fertilization.

Plant Cultivation. The selection of species and varieties and the planning of the entire rotation are crucial factors in reducing economically and ecologically undesired nitrogen losses. The *evergreen system,* that is, keeping fields covered with crop plants year-round, is a desirable goal; whenever possible, the intercrops should moderate N fertilization (nitrogen harvesting). This practice also protects against erosion. Fallow land should be avoided; semifallow area, such as under corn, sunflowers, or summer grains, should be minimized.

An extraordinary reduction of nitrate loss by leaching is achieved by overhead crop irrigation, and, the extreme case, by moderate spraying to avoid frost damage and possibly the loss of a crop in an early stage.

Plant Protection. Plant protection measures, whether mechanical (especially to combat weeds and grass), biological, or chemical, generally increase yield and thus better utilize the nitrogen supply. In this way they indirectly reduce ecologically undesirable nitrogen losses.

Plant Breeding. Nitrogen-efficient plant species and varieties produce more dry matter per unit of nitrogen delivered than do inefficient species.

Soil Tillage. Tillage also has a decisive effect on ecologically undesirable N losses. Tilling as deep as possible, while still preserving soil structure, aids the availability of the nitrogen and reduces the leaching loss by creating the optimal pore volume in combination with an ordered humus regime, thus optimizing the water regime and the supply of water to the crop.

9.2. Phosphorus

Environmental problems connected with phosphate fertilizers are eutrophication and the buildup of heavy metals.

9.2.1. *Eutrophication*

The pollution of nonflowing or low-circulation surface waters (lakes, estuaries, and coastal zones, especially tidal mud flats) with plant nutrients is to be avoided on account of eutrophication. This term refers to the excessive growth of algae and aquatic plants due to too great a supply of nutrients. Because the putrefaction of these organisms requires a great deal of oxygen, the water becomes depleted in oxygen. Fish die, and the biological purification of the water ceases to function. The lake has *turned over.*

The primary limiting factor for eutrophication is phosphate. Surface waters should contain ≤ 50 µg P per liter. Nitrogen can also become a factor for eutrophication when increased biomass growth takes place.

Figure 46 compares the amounts and main sources of phosphates in surface waters of Germany from 1975 to 1995 [554]. The P input by point sources was markedly decreased by improved sewage treatment practices and by the transition to phosphate-free detergents. Consequently, the share of diffuse sources in the total P input increased from nearly 20 % to about 50 %, although the absolute diffuse input also began to fall from ca. 1990 onwards. Soil erosion and surface runoff from agricultural fields are the most important diffuse sources (Fig. 47).

Figure 46. Changes in phosphorus input into surface waters in Germany from 1975 to 1995 [525], [526], [552], [554], [614], [615]

Figure 47. Nitrogen and phosphorus inputs into running waters by diffuse and point sources in Germany: prognosis for 1995 [553]

In contrast to nitrogen, phosphorus pollution via groundwater and drain water is not yet important, although vertical transport of this nutrient may create a pollution problem where the P sorption capacity of deeper soil layers is already highly saturated. This has been reported for areas with high livestock densities in the Netherlands [616] and in north-western Germany [617].

The agricultural contribution to phosphorus in surface waters on a regional scale makes the implementation of efficient countermeasures in agriculture necessary [618], [619]:

- Prevention of erosion by field arrangement (e.g., reducing the slope length), crop management (mulched seeding, underseeding, changes in crop

rotation), and soil management (tilling across the slope, improvement of soil structure and infiltration rate).
- Prevention of surface runoff from slopes by omitting the application of mineral or organic fertilizers in autumn and winter.
- Prevention of direct inputs of eroded soil and runoff water by planted margins along the banks of surface waters.
- Consequent adjustment of phosphorus fertilization to plant requirements: supply and removal must be kept in balance on soils with optimum P supply status. On P-accumulated soils, fertilization can temporarily be reduced or even omitted.

In Germany, the implementation of countermeasures is accelerated by the German “Fertilizer Utilization Decree” of 1995.

Besides economic reasons, environmental concerns were also responsible for changes in mineral fertilizer consumption since 1985. As far as phosphorus is concerned, the balance surplus showed a mean annual decrease of 7 % for the period of 1990 – 1995 [551], in particular due to reduced application of mineral P fertilizer (mean application 11.0 kg P/ha in 1995 compared to 25.5 kg P/ha in 1985).

9.2.2. *Heavy Metals Buildup*

With regard to the impact of fertilizer use on heavy metals buildup in soils, the element cadmium is of primary concern. Fertilizer phosphates produced from phosphate rock contain cadmium [7440-43-9]. The amount depends on the origin of the rock and the digestion process employed. The cadmium content of phosphate rock varies from almost zero to about 700 mg/kg P. The acidification of phosphate rock partitions the Cd between the fertilizer and byproducts of phosphoric acid production such as phosphogypsum.

The Cd input into agricultural land by phosphate fertilizers in Germany was significantly decreased during the last two decades, due to both the preference of low-cadmium phosphate rock for fertilizer production and the dramatic decrease in mean phosphorus application rates. The mean Cd content is phosphorus fertilizers is now reported with about 100 mg/kg P [620]. The mean application rate in 1995/1996 was 11 kg P/ha. Based on these figures, the average annual Cd input is 1.1 g/ha, which compares to about 3.0 g/ha in 1980.

The quantities removed by the crops and by leaching are calculated at about 2.0 g Cd/ha. The background Cd contents in agricultural fields therefore, could not be augmented by mineral fertilizers alone, even if current application rates were doubled [621-623]. However, additional cadmium sources must be taken into account. Atmospheric input from industrial air pollution is the most important source in all industrial countries (3 – 6 g Cd/ha). Manures, sewage sludges, and biowaste composts may be locally or regionally important heavy metal sources [624]. Legal regulations in Germany allow annual maximum heavy metal inputs into soils that are much higher than the realistic inputs via mineral fertilizers. For cadmium these threshold values are 18 g/ha by atmospheric depositions, 10 g/ha by biowaste composts or 16.7 g/ha by sewage sludges.

[Top of Page]

10. Legal Aspects

Günter Kluge

Since the beginning of the mineral fertilizer industry, many countries have issued regulations to protect fertilizer users. These rules deal, in particular, with nutrient contents and with safety for plants, human beings, animals, and the environment.

Fertilizer regulations are based on special fertilizer legislation or else form part of a more comprehensive regulatory scheme that governs areas such as animal feeds or pesticides. As a rule, the government department of agriculture has jurisdiction over fertilizers.

The rules on fertilizers extend only to commerce in fertilizers (offering, selling, trading); in only a few cases do they cover other areas (Table 38).

Definition. Laws on fertilizers either contain a definition or simply refer to a list of fertilizers. A definition may be scientifically or pragmatically oriented. While mineral fertilizers present fewer difficulties, the diverse agents used for soil amendment are harder to define.

Examples:

Material, the main function of which is to provide plant food. (ISO)

The term “fertilizers” as used within this Law shall be defined as being any substance applied to the soil for the purpose of supplying nutrients to plants; for producing a chemical change in the soil which will contribute to the cultivation of plants; or which, when applied to the plant, will supply plant nutrients. (Japan)

Fertilizers are substances that are intended to be supplied directly or indirectly to crop plants in order to promote their growth, increase their yield, or improve their quality; excepted are . . . (Federal Republic of Germany)

In the regulations and annexes, fertilizers are systematically classified, for example, into straight and multinutrient fertilizers. The physical form, for example, in liquid fertilizers, may also figure in the classification.

Approval, Registration, Type Lists, Standards. In principle there are two ways of regulating the trade in fertilizers: type approval and individual approval of fertilizers. The European Economic Community (EEC) has chosen the following approach in the interest of harmonization of laws: A type list describes the fertilizers covered (type designation, minimum nutrient contents, expression of nutrients, method of production, essential ingredients, nutrient forms, and

nutrient solubilities). Fertilizers that meet these requirements may be marketed provided the labeling rules in all member states are complied with.

Such a system exists in similar form in many of the developed countries. Allowance is made for the fact that many fertilizers are products well known in international trade, such as urea, triple superphosphate, and NPK fertilizers. The administrative cost is low. The type list must be supplemented from time to time to take account of technical development. As a rule, effectiveness must first be proved (plant tests), as must safety for human beings, animals, the soil, and the environment.

Another approach is individual licensing for each fertilizer offered by a manufacturer or importer. An administrative action must precede the sale of any product. The government thus has a complete picture of the registered fertilizers and of the suppliers. Often, approval is granted only for a certain time. Provisional approvals are usually possible.

Because both systems have advantages and drawbacks, many countries prefer a mixed approach: type approval and registration. Standards are defined for fertilizers. Manufacturers and importers must seek registration, which requires stated tests. The certificates granted often have only a limited term.

The choice of approach is dictated, above all, by the system of laws and government in each country, in particular by the degree of supervision desired by the state.

Labeling, Terminology, Packaging. Next to approval, labeling of the product on the package or accompanying documents is the most important rule. The prescribed manner of labeling varies greatly from country to country. Before doing business, it is therefore vital to have an exact knowledge of these regulations. In general, the following information is required as a minimum:

1. type designation or name of the fertilizer
2. guaranteed content of each nutrient
3. name and address of the person responsible for sale
4. weight of product

Special rules apply to trademarks and trade names. There are special rules for packaging and sealing; most of these are restricted to certain fertilizers.

Official Inspections, Sampling, Analysis. As part of the supervision of fertilizer marketing, the sampling and analysis methods to be employed in official inspections are set forth. The variety of methods and their continual development make a selection for official tests necessary. The official checking of the guaranteed nutrient contents must be governed by rules that state whether and to what extent, unavoidable deviations are tolerated. For example, the EEC has adopted definite unified tolerances for each type of fertilizer.

Fertilizer legislation also includes the action to be taken when violations occur (fines, seizure).

Finally, besides the special laws pertaining to fertilizers there are also provisions in other areas of legislation that must be observed in the fertilizer market. The regulations on transportation and storage and the rules aimed at preventing epidemics, important for organic fertilizers, should be kept in mind.

[Top of Page]

11. Economic Aspects

Friedrich Kuhlmann, Hugo Steinhauser, Walter Brändlein, Karl-Friedrich Kummer

Consumption, production, and international trade of fertilizers are determined by technical, economic and legal factors, i.e., by output – input efficiencies, factor and product prices, and legal constraints. This applies to the single plot of an individual farm up to the agricultural area of entire nations and continents. While in developing countries consumption of fertilizers is still growing, in developed countries environmental concerns are making themselves felt, leading to legal and economic disincentives against unduly high fertilization rates. However, because of sustained world population growth, world consumption of mineral fertilizers will further increase within the next decades.

11.1. Economics of Fertilization

11.1.1. *Input – Output Relationships: The Yield Function*

Assessing economic benefits of fertilization is a relatively complex task, since the outputs of crop production processes are determined by numerous input factors, affecting the output level and being interdependent among each other. The precondition for economic considerations, therefore, is quantitative knowledge about (crop) yield functions. Although at present this knowledge is still not complete, it can safely be stated that plant growth obeys basic laws of nature, especially chemical laws. The relevant yield function for a crop — as JUSTUS LIEBIG first showed with his “law of minimum” — can thus be written as:

$$y = \min\{b_1x_1;\ \ldots\ b_jx_j;\ \ldots\ b_mx_m\} \tag{1}$$

y = amount of crop output
x_j = supply of necessary inputs
b_j = partial output – input coefficients

The x_j comprise inputs which are controllable by the farmer (seed, fertilizers, pesticides, etc.), as well as those which are not controllable (solar energy, genetic yield potential, water in rainfed agriculture, etc.). The output level y is determined by the input whose supply is minimal compared to all other inputs. Given certain supplies of all but one particular input, the output increases proportionally with increasing supply of this input, until some other input becomes the minimum factor. Further augmentation of the variable input does not lead to any further output; it would be wasted. When a fertilizer is the variable input, the relationship is called a linear response and plateau function (LRP function; Fig. 48) [627].

Figure 48. Types of yield function

The LRP function, however, is not compatible with results of fertilizer field experiments, investigated by means of regression analysis [628-630], [640]. Usually, these empirical investigations lead to curves shaped according to the “law of diminishing returns” (LDR function; Fig. 48). The difference between the two types of response function can be explained by the fact that available supplies of one or more of the other inputs vary from plant to plant in a plot (e.g., genetic potential, water) [641-643].

To simplify further discussion, it shall be assumed that the output (e.g., wheat) is only restricted by two inputs: the variable input x_v (e.g., nitrogen) and a given input x_g, whose amount varies randomly from plant to plant (e.g., genetic potential). Equation (1) then simplifies to:

$$y = \min\{b_gx_g;\ b_vx_v\} \tag{2}$$

Assuming a discrete distribution for the amounts of x_g, Equation (2) can be expanded to:

$$y = \sum_{i=1}^{n} p_i \min\{b_g x_{gi};\ b_v x_v\} \text{ with } \sum_{i=1}^{n} p_i = 1 \quad (3)$$

y = wheat output in dt/ha
i = number of classes in the discrete distribution of the genetic potential
p_i = probabilities of the different classes of the discrete distribution
x_{gi} = genetic potentials of the plants in the different classes of the discrete distribution, measured in dt/ha
x_v = variable supply of nitrogen, measured in kg/ha
b_g, b_v = partial input – output coefficients

If, e.g., i = 5, p_i = [0.1; 0.2; 0.4; 0.,2; 0.1], x_{gi} = [20; 40; 60; 80; 100], b_g = 1 and b_v = 0.33, increased amounts of nitrogen (in steps of 40 kg/ha) result in the plot yields shown as dots in Figure 48. Applying regression analysis leads to the LDR function also depicted. Although each plant grows according to a LRP function, the analysis of this small “experiment” suggests a law of diminishing returns.

The shape of the LDR function depends upon the variance of the spatial distribution of the input x_g within a plot. A smaller variance produces LDR curves that more closely resemble the LRP function. When the variance approaches 0, the LDR function transforms into a LRP function. This relation is especially important because modern plant breeding has reduced genetic variance of varieties (sometimes to zero), and modern land cultivation has homogenized soil conditions.

11.1.2. *Factors Controlling the Optimal Nitrogen Fertilization Level*

The above relation is of essential importance in determining the economically optimal supply of the variable input nitrogen. Assuming the LDR function of Figure 48, a wheat price of 11 €/dt, a nitrogen price of 0,6 €/kg, and a nitrogen delivery from the soil of 80 kg/ha, the optimal nitrogen fertilization rate can be derived as shown in Figure 49. The farmer tries to maximize the difference between the monetary return (LDR_1) and the nitrogen costs (NC_1). This maximum is obtained at the nitrogen input level (Nop_1) for which the slope of the monetary return curve equals the (constant) slope of the nitrogen cost line, that is, when marginal monetary returns equal marginal nitrogen costs [631].

Figure 49. Economically optimal nitrogen supply in crop production, assuming the law of diminishing returns (LDR function)

Changes of output and/or input prices lead to different optimal nitrogen input levels and profitabilities. For example, doubling the wheat price to 22 €/dt results in the monetary return curve LDR_2. Tripling the nitrogen price to 1,8 €/kg results in the cost line NC_2. The first variation leads to the increased optimal nitrogen supply level Nop_2, the second variation to the decreased optimal nitrogen supply Nop_3. Generally speaking, increasing crop prices and/or decreasing factor prices result in higher fertilizer consumption, and vice versa.

If, however, the crop yield responds to variable nitrogen input levels according to an LRP function, then the farmer who tries to maximize the profitability would always provide the same nitrogen input level, regardless of price situations. Figure 50 shows monetary return functions for wheat prices of 11 €/dt (LRP_1), and 22 €/dt (LRP_2). In addition, the nitrogen cost lines, repeated from Figure 49, are depicted. Clearly, for all price situations the farmer would try to ensure the same optimal nitrogen input level Nop_1.

Figure 50. Economically optimal nitrogen supply in crop production, assuming linear response and plateau functions (LRP functions)

In modern agriculture, the yield functions are approaching LRP functions, so that price variations have less and less impact on levels of fertilization.

11.1.3. *Factors Influencing the Optimal Nitrogen Fertilization Level*

As can easily be derived from Equation (1), other factors, especially the levels of noncontrollable inputs for plant growth, exert a substantial influence on the optimal nitrogen input level. Firstly, the soil and climate conditions of a particular piece of land play a major role. Increased availabilities of solar energy and/or plant-available water allow for more productive fertilizer consumption, returning higher yields. As an example, Figure 51 shows the nitrogen response functions LRP_1 and LRP_2 for two parcels of land with different water conditions. The higher optimal yield y_2 of the “better” parcel can be obtained only if the nitrogen supply is increased from Nop_1 to Nop_2. Water and nitrogen are complementary inputs with respect to crop yield.

Figure 51. Effects of increased yield potentials on nitrogen requirement

Secondly, modern plant breeding successively produces varieties with higher yield potentials, enabling the plants to consume water and/or solar energy more effectively. This, of course, leads to higher yields, provided the fertilizer input level is increased appropriately. Figure 51 may be also interpreted in terms two varieties of different productivity.

Thirdly, modern crop-protection agents keep the plants healthy during the vegetation period, enabling them to consume more solar energy and water. This again leads to higher yields, provided the fertilizer input level is adjusted accordingly. The situation with and without the application of modern pestizides can also be represented by the LRP functions of Figure 51.

Under a wide range of price situations, the farmer would make full use of favorable soil and climatic conditions, as well as of the advantages of improved seeds

and crop-protection agents. As a rule, the additional monetary returns of the increased yields are much higher than the additional costs for fertilizers, seeds, and pesticides.

11.1.4. *Environmental Aspects of Fertilization*

Ecological concerns with respect to fertilization are becoming more and more important. They arise from the fact that farmers apply more fertilizers than may be consumed productively by the crops. Depending on soil conditions, some part of the surplus will not be stored in the soil to be used by the following crop, but will be leached into the underground, eventually contaminating the ground water.

However, even state-of-the-art fertilization causes some nitrogen surplus. This is due mainly to two facts: First, as discussed above, the levels of certain noncontrollable plant growth inputs are distributed randomly over a plot of land. Since the farmer does not know the exact locations, he will fertilize the whole field evenly or, in case of precision agriculture methods, at least larger parts of it. He will try to provide a nitrogen level such that the average marginal costs for the plot are equal to the average marginal monetary returns. Unavoidably, there will always be some low-yielding spots which receive too much fertilizer.

Second, under most climatic conditions for rainfed agriculture, plant-usable water supply varies from year to year. Since the farmer does not know the water supply of a particular year in advance, he will always “shoot” for a “good” year. If, for example, in a good year the higher yield y_2 in Figure 51 is achievable, and in a “dry” year only the lower yield y_1, the farmer will nevertheless always provide for the higher nitrogen level Nop_2 instead of the lower level Nop_1. The reason is simple: the expected profitability value of strategy Nop_2 is under realistic price and weather conditions much higher than that of the strategy Nop_1.

If the farmer provided only for the low fertilization level Nop_1, in a good year he would lose the monetary return of 20 dt/ha (see Fig. 51), because the insufficient nitrogen supply would limit the yield. At a wheat price of 11 €/dt, this corresponds to a loss of 220 €/ha. At the higher nitrogen level Nop_2, in a dry year 60 kg/ha nitrogen would be wasted (Fig. 51). This corresponds to a loss of 36 €/ha.

These economically induced fertilizer surpluses can be reduced by further improvements of inputs, production techniques, and prognostic information. Seed varieties with less genetic variance and homogenization of soil conditions lead to less variance of the noncontrollable growth factors within a field. Splitting nitrogen fertilization into several applications as the vegetation period develops and new information about the water supply becomes available also reduces waste of nutrients. Finally, improved long-term weather forecasts would be most valuable in reducing the uncertainty involved in fertilizing decisions.

Strict legal constraints for nitrogen application rates, however, would not be the strategy of choice. It would lead to a waste of valuable yield potential and in addition to economic losses for farmers.

11.2. World Consumption, Production, and Trade

Consumption. World consumption of the three primary nutrients — nitrogen, phosphate and potash — reached a total of 135.0 × 10^6 t in 1996/97. The previous record level of 145.6 × 10^6 t in 1988/89 was once again not reached. The consumption figures broke down as follows [625] in 10^6 t:

Nitrogen	82.9 N
Phosphate	31.1 P_2O_5
Potash	21.0 K_2O

Over the past 10 years, agricultural consumption of fertilizers experienced a deep recession, mainly due to developments in Central and Eastern Europe, as well as in the former Soviet Union. World consumption fell by 17 % from 1988/89 to 1993/94 and then recovered by 12 % up to 1996/97. Over the ten year period, nitrogen increased by 16 %, phosphate fell by 10 %, and potash fell by 19 %.

The consumption ratio N : P_2O_5 : K_2O was 1 : 0.6 : 0.5 in 1976/77; it changed in favor of nitrogen to 1 : 0.5 : 0.4 in 1986/87, and in 1996/97 it reached 1 : 0.4 : 0.25. While in North America and Western Europe the ratio is 1 : 0.4 : 0.4, it is less well balanced in other regions of the world (Table 39). Fertilizer consumption and production are given for fertilizer years, running from 1 July to 30 June. For example, 1996/97 is the period from 1 July 1996 to 30 June 1997.

Table 39. World nitrogen, phosphate and potassium consumption in millions of tonnes over the period 1976/77 – 1996/97 broken down by region/country [625] [*]

[**] Excluding Asian republics of former Soviet Union.

In case only calendar year figures are available, e.g., 1996 is summarized under 1996/97. A regional analysis of fertilizer consumption shows that over 60 % is used in developing countries (in Asia, Latin America, Africa). The Asian markets are particularly important. About 50 % of all fertilizers consumed are applied in Asia. North America takes second place with 17 %, followed by Western Europe. Three decades ago, Western Europe was the world's largest fertilizer consumer; after 10 years, the Eastern Bloc had overtaken Western Europe; and another 10 years later, the developing countries have taken the lead — having increased their consumption tenfold in 30 years. This change corresponds to a mean annual growth rate of 8 %.

The intensity of fertilizer use, however, is still greatest in Western Europe. In terms of nutrient per hectare of agricultural area, Western Europe averaged 121 kg applied in 1996/97 (Table 40). The corresponding figure for the developing countries is 24 kg. In these countries, however, virtually no fertilizer is applied to pastureland. If the figures are referred to agricultural area minus pastureland, the rate in the developing countries was 88 kg of nutrients per hectare, 56 kg of this being N. Fertilizer application is extremely low in the former Soviet Union (8 kg/ha).

Table 40. Nutrient use per hectare of agricultural area, [625], [632]

Region	Nutrient application, kg/ha			
	N	P_2O_5	K_2O	Total
Western Europe	67.6	24.7	28.8	121.2
Central/Eastern Europe	36.1	10.6	9.9	56.6
Former Soviet Union	4.8	1.5	2.1	8.4
North America	26.0	9.8	10.5	46.4
Other	15.2	5.8	2.7	23.6
World average	16.9	6.3	4.3	27.5

[a]Consumption: FAO Fertilizer Yearbook, Agricultural Area: FAOSTAT Database results

Three countries account for over half of world fertilizer consumption: China with 36.6 × 10^6 t, the United States with 21.2 × 10^6 t, and India with 14.3 × 10^6 t. Next on the list are India with 14.3 × 10^6 t, France with 5.1 × 10^6 and Brazil with 4.8 × 10^6.

In years to come, a further worldwide increase is expected. This growth will take place chiefly in Asia, Latin America and Africa. The recovery of fertilizer use in Central/Eastern Europe and the former Soviet Union is anticipated but will take time.

Production. A survey of production in 1996/97 showed that Asia ranks first as world fertilizer producer, mainly for nitrogen, but also for phosphate fertilizers, followed by North America, the leading potash producer (Table 41).

Table 41. World fertilizer production by nutrient and region 1996/97 [625]

World supply [**]	72.6	85.8	34.9	32.2	26.1	21.8	133.6	139.7

* Excluding Asian republics of former Soviet Union.
** Available world supply was arrived at by deducting from production estimated amounts for technical uses, further processing, transport, storage, and handling losses.

Over the past ten years the production pattern by region shows a considerable decrease in Western and Central/Eastern Europe (– 27 % and – 37 %, respectively) but above all in the former Soviet Union (– 50 %). In North America (+ 27 %) and especially Asia (+ 61 %) production increased markedly. While overall world production remained nearly stagnant (+ 3.5 %), nitrogen production increased by 18 %, but phosphate and potash dropped by 8 % and 16 %, respectively.

The leaders in production of fertilizers are China, the United States, and India. They are followed by Canada, the world's largest potash producer, and Russia (Table 42).

Table 42. Fertilizer production by country, 1996/97 [625]

Country	Fertilizer production, 10^6 t

Canada	2.7 *	0.4	8.1	11.2
Russia	4.9	1.6	2.6	9.1

* Author's estimate (available supply)

The rise in fertilizer production and consumption in recent decades could not have taken place without an enormous technical advance. Significant cost savings in ammonia production, the intermediate for nitrogen fertilizer production, resulted from the changeover from multi-train to single-train plants and the conversion to more economical feedstocks, mainly natural gas.

Due to improved product quality and well-balanced particle size spectrum, rational bulk transportation and easier application become possible. Higher analysis fertilizer grades brought savings in shipping and storage per unit of nutrient.

The fertilizer processes were optimized to decrease energy consumption. Emission reduction with modern techniques improved the environmental performance of the processes and at the same time increased the nutrient yield from the raw materials. These improvements are of great importance: the 149 × 10^6 t of nutrients produced worldwide in 1996/97 meant 430 × 10^6 t of fertilizers that had to be stored, transported, and applied (authors estimate).

World Trade. Recent decades have seen a sharper rise in world trade than in consumption. Because of the limited number of potash deposits, the ratio of trade to consumption is highest for potash, with 91 %. Some 40 % of phosphate and 29 % of nitrogen are sold internationally (Table 43).

Table 43. World fertilizer trade in millions of tonnes (exports) (10^6 t) [625] *.

Total	26.6	44.5	55.7

* *FAO Fertilizer Yearbooks*

In nitrogen, Russia and the USA have the largest exports, but Canada, Ukraine, and the Netherlands are also important in the world market. The most important importing regions are China and the USA.

American exporters dominate the phosphate market, with sales in all regions, but primarily in the developing countries in Asia, Latin America and Africa. The largest exporters of potash are Canada and Germany, followed by Belarus and Russia.

The largest exporters and importers in 1996/97 are listed in Table 44.

Table 44. Major exporting and importing countries for nitrogen, phosphate, and potash fertilizers, 1996/97 [625]

* Author's estimates.

Types of Fertilizers. As the quantities produced and applied have increased, the importance of fertilizer grades has changed. Low-analysis grades have decreased, while highly concentrated grades such as urea, triple superphosphate, and NPK fertilizers have gained (Fig. 52). Sulfur-containing fertilizers have gained importance to cope with sulfur deficiencies.

Figure 52. World fertilizer consumption by type, 1996/97 preliminary [632]

A) Nitrogen fertilizer; B) Phosphate fertilizer; C) Potassium fertilizer

Urea has become the preferred nitrogen fertilizer, especially in the developing countries. In Western Europe, for example, ca. 80 % of nitrogen consumption is in the form of ammonium nitrate, calcium ammonium nitrate, and ammonium nitrate-based multinutrient fertilizers. Phosphate consumption is dominated by multinutrient fertilizers. In the case of potash, straight potassium chloride is the most important grade, but potassium sulfate is of growing importance due to its sulfur contents.

11.3. Future Outlook

The decisive factors for the development of fertilizer demand are population growth and changes in the available income per capita. A growing world population needs more food and fiber. In addition, a wealthier population has a higher daily energy intake per capita and it generally consumes a higher share of animal products (Table 45). Compared to direct human consumption, three to four times more plant products such as cereals are necessary to produce the same amount of energy in the form of animal products like milk, eggs, and meat.

Table 45. Dietary energy supply per capita by economic group 1969 – 1971 and 1990 – 1992 [633]

Country Group	Total kcal/d		% animal	
	1969 – 71	1990 – 92	1969 – 71	1990 – 92
Industrialized	3120	3410	30.4	29.8
Transition	3330	3230	24.4	27.6
Low-income	2060	2430	6.1	9.3
Least developed	2060	2040	6.6	6.0
World	2440	2720	15.6	15.7

11.3.1. *Food Situation*

Since the 1950s world food production per capita has continuously increased, although world population has more than doubled (from 2.5 to almost 6.0 billion). New crop varieties and improved production techniques enabled a substantial growth of average yields. A significant advance was the broader use of effective cereal fungicides in industrialized countries and the introduction of high-yielding varieties of rice, wheat, and maize in several developing countries, known in the 1970s as the “green revolution”. These varieties, bred for tropical and subtropical regions, already offer a higher yield potential under traditional growing conditions. But their full potential can only be exploited when crop husbandry and plant nutrition are adapted to their needs, and agrochemicals provide protection against insects, diseases, and competition from weeds. In many cases they rendered the use of fertilizers and agrochemicals economic for the first time. The average yields of cereals, the most important staple food of humans, increased substantially (Table 46).

Table 46. World production and average yields of cereals 1972 – 1974 and 1996/97

	Production, 10^6 t		Yield, t/ha	
	1972 – 74	1996 – 97	1972 – 74	1996 – 97
Wheat	359	581	1.66	2.53
Maize	300	562	2.75	4.02
Barley	164	155	1.88	2.33
Rye, Oats	81	54	1.68	1.85
Rice	325	558	3.23	3.76
Total	1229	1910	2.19	3.11

According to the FAO, on average each kilogram of fertilizer nitrogen applied to the soil produces about 12 kg of cereal units (1 kg of cereal unit is equal to the nutritional value of 1 kg of barley); therefore, it can be calculated that the food for half of the world's population can only be provided due to the use of (75 – 80) × 10^6 t nitrogen in mineral fertilizers annually. Nevertheless, 840 million individuals still suffer from undernutrition and an estimated 20 million die annually of hunger and undernutrition-related diseases. Civil wars, natural disasters, and poverty, often related to unemployment, are the main reasons for starvation.

Growth in Food Demand. The 1996 update of the UN World Population Prospect shows that the rate of world population growth has declined to 1.48 % per

annum, but this still means an additional 80 million humans to be fed every year. By the year 2020 world population is predicted to reach 7.67 billions. Since economic growth is expected to continue, a larger part of the population will be able to spend more money on food. Thus an increased demand per capita for plant products to be used as animal feed must be taken into account. The demand for cereals is expected to increase by 41 % from 1993 to 2020, that for meat by 63 %, and the consumption of tubers and root is estimated to rise by 40 % [634].

Agricultural Land Use. More than 70 % of the world's surface is covered by water. Of the 13.4 billion hectares of dry land, 4.7 billion hectares are used by agriculture. The major portion is covered by extensively used grasslands, often in low-rainfall areas. Most of the food is supplied by the 1.4 billion hectares of arable land — a mere 10 % of the dry land. Much of the remaining area is not suitable for intensive agricultural production since it is either too dry, too steep, too cold, or infertile. The majority of soils usable for arable crops are covered by biotopes such as rain forests. There is no agreement to which extent they should be used for agriculture and how much must be preserved. FAO [635] calculated that Sub-Saharan Africa and Latin America have the most land reserves with crop-production potential.

At the same time 7 million hectares agricultural land are lost annually due to erosion and salination. The agricultural area available per capita declined from 0.44 ha (1960) to 0.27 ha (1990) and is expected to shrink further to 0.17 ha by 2020. Therefore FAO estimates that although newly cleared land may supply 21 % of the necessary increase in food production, and more frequent use of existing arable land 13 %, the most important contribution (66 %) must come from higher yields on soils already under cultivation. Although neither the quality of soils nor the agroclimatic conditions will allow the same high yield to be achieved everywhere, the wide variation in actual yields offers a vast potential for further improvement (Figure 53).

Figure 53. Average nutrient application rates (kg N + P_2O_5 + K_2O per hectare) and average yields (t/ha) of countries with high, medium, and low fertilizer application rates in 1995 [636]

Intensity of Agricultural Production. The intensity of agricultural production is highest in industrialized and transition economies, where the purchasing power for food is high. Attractive markets create an efficient production system, whereas the subsistence farmer cannot invest in yield-raising inputs. Annual nutrient application rates therefore vary widely (Figure 53). Western European countries, Egypt, Saudi Arabia, and Mexico for example apply on average more than 200 kg N + P_2O_5 + K_2O per hectare wheat and harvest 4 – 7 t of grain, whilst countries using less than 50 kg plant nutrients obtain barely more than 2 t per hectare [636]. This of course can also be the result of unfavorable growing conditions, primarily insufficient supply of water, but for most countries it reflects the socio-economic situation.

Wheat is the crop which receives most (22 %) of the fertilizer nutrients, followed by rice and maize (17 % each). Cereals in total count for 65 % of the nutrient consumption, while 9 % are used on oil crops, 5 % each on vegetables and sugar beet/cane). Thus, fertilizers are predominately used for food production. Fiber crops, tobacco, and stimulants receive 4 and 2 %, respectively [636].

In the past countries with economic and population growth have increased their fertilizer consumption (Table 47), whereas those with traditionally high consumption only show moderate growth (e.g., United States, Canada, Spain) or a decrease in consumption. This is the case for most EU countries, where nutrient levels in the soil have mostly been built up to the desirable level, environmental concern has led to strict regulations, and changes in agricultural policy, such as leaving arable land fallow, have been introduced. Changes of the economic system in the former centrally planned economies resulted in a dramatic decline in agricultural production and consequently in fertilizer consumption.

Table 47. Development of fertilizer use in the 20 countries with the highest actual nutrient consumption 1985/86 – 1995/96 in 10^6 t N + P_2O_5 + K_2O [637]

	1985/86	1995/96
China	16 852	35 527

11.3.2. *Development of Fertilizer Consumption*

World fertilizer consumption will continue to rise by more than 2 % per annum from 1996/97 to 2002/03 [638], [639]. The rate of growth will be highest in the densely populated countries of South Asia (+ 5.2 %), in Latin America (+ 5.0 %), Africa (+ 4.9 %) and Central Europe (+ 4.4 %) (Figure 54). The estimated increase in Central Europe signals a recovery from economic depression, while the growth rate in Africa simply reflects the low base. For Western Europe, a further decline in fertilizer consumption is forecast since the agricultural area in this densely populated, industrialized region will continue to decline, and more efficient use of organic manures (farmyard manure, sewage sludge, etc.) will be necessary to achieve the goals set for the protection of the environment.

Figure 54. Fertilizer consumption forecast by region 1995 – 2002 [638]

The optical fiber is one of the most important key technologies that support the current information technology (IT) era. Optical fibers are now widely used not only as an excellent transmission medium for optical communication but also as optical functional devices, such as optical amplifiers. Both optical fibers and their manufacturing technologies have evolved dramatically toward higher performance and improved productivity. Their applications have also been expanded from optical communication to a variety of fields, such as optical sensors. This article reviews various aspects of optical fibers: structures & materials, fabrication techniques, optical characteristics & reliability, and applications.

1. Introduction

The oldest scientific record concerning light transmission in a confined path is attributed to the British physicist J. TYNDALL who, in 1870, studied the transmission of light in a curved stream of water. In 1930, the German physicist H. LAMM conducted experiments on image transmission through a crude assembly of quartz fibers. In 1936, G. C. SOUTHWORTH, in the United States, carried out theoretical and experimental studies on the behavior of electromagnetic waves in cylindrical nonconductive materials; in the late 1950s, T. NAKAHARA made a theoretical and experimental study on a loosely bounded electromagnetic wave along variously shaped dielectric lines using quasi-millimeter waves [1]. The phenomena they observed are exactly the same as those encountered in the transmission of laser light through optical fibers.

In the 1930s, many physicists studied the transmissivity of materials (e.g., F. URBACH, K. A. STACEY, and B. SZIGETY). They observed peaks in light absorption in the infrared region, which suggested the existence of a band with low absorption and thus a low transmission loss between the ultraviolet and infrared regions.

An optical communication method using glass as a transmission medium had been proposed in Japan in 1936 [2]. In the early 1960s, optical waveguides using lenses or lenslike media for optical signal transmission were studied by Bell Laboratories in the United States. KAO and HOCKHAM [3] of Standard Telephone Laboratories (STL) in the United Kingdom demonstrated in 1966 that removal of impurities from glass fibers reduced the loss (attenuation) of optical transmission to a level acceptable for use in long-distance communications; they recommended quartz as a suitable transmission material. In 1968, KAWAKAMI and NISHIZAWA [4] proposed that an optical fiber with a refractive index distribution similar to that of a lens could be used effectively as a high-capacity transmission medium.

Methods for fabricating transparent, pure fused silica glass have been in use since 1910. In 1935, a method of producing synthetic silica glass was developed, based on the decomposition of volatile silicon compounds such as silicon tetrachloride [10026-04-7]. Furthermore, by the early 1960s, the discovery had been made that the refractive index of pure fused silica glass could be increased easily with various additives; the structure, materials, and characteristics of a suitable optical fiber for signal transmission had also been described on a theoretical basis.

In 1969, Nippon Sheet Glass and the Nippon Electric Corporation (NEC) jointly produced a graded-index multicomponent glass fiber, which they called Selfoc, using an ion-exchange process [5]. In the first trial production, the light attenuation of the fiber was 80 to 200 dB km^{-1}. In 1970, Corning Glass Works in the United States announced a silica fiber with an attenuation of 20 dB km^{-1} [6], which was manufactured by depositing a particulate TiO_2–SiO_2 glass layer inside a silica tube by flame hydrolysis. In 1974, Bell Laboratories reported the production of a low-loss fiber with an attenuation of 1.1 to 2 dB km^{-1} by modified chemical vapor deposition (MCVD) [7]. The method of outside vapor deposition (OVD) was announced by Corning Glass Works in 1973 [8]. Sumitomo Electric filed a continuous vapor-phase axial deposition process patent that covered an arbitrary refractive index profile in 1974. Philips reported the plasma chemical vapor deposition (PCVD) method in 1975 [9]. The Nippon Telegraph & Telephone Corporation (NTT) announced the development of the vapor-phase axial deposition (VAD) process for step-index profile in 1977 [10]. The VAD process was rapidly improved, leading in 1981 to the successful manufacture of long, uniform optical fibers whose light attenuation was 0.2 dB km^{-1}.

The theoretical transmission loss of a silica fiber at a wavelength of 1.55 µm is about 0.13 dB km^{-1} and is limited by Rayleigh scattering and the vibrational absorption of the Si—O bonds. After the development of fluorine-stuffed pure silica fiber announced in 1972, the transmission loss was decreased. Champion data of transmission loss 0.154 dB km^{-1} at 1.55-µm wavelength and 0.1484 dB km^{-1} have been recorded in 1986 and in 2002, respectively [11].

As for mechanical strength, ordinary manufacturing equipment could not be used owing to the extreme brittleness of silica fiber. Sufficient mechanical strength for practical use could not be attained by applying polyamide (nylon) extrusion to drawn

fiber. However, the development in 1974 of the method of tandem resin coating immediately after drawing dramatically improved the mechanical strength [12].

2. Structure of Optical Fibers

2.1. Basic Structure

Optical fibers consist of a central core and a cladding layer that surrounds the core. The core has a slightly higher refractive index than that of the cladding. The transmission of light in the optical fiber is illustrated in Figure 1.

Figure 1. Fundamental structure of an optical fiber

n_1 = refractive index of core; n_2 = refractive index of cladding; θ = angle of reflection at core–cladding interface; φ = launching angle

When light is launched into the core at the endface of the optical fiber, the portion of the light whose angle is within a certain range will be trapped inside the core by total internal reflection at the core–cladding interface. The critical angle for the total internal reflection depends on the refractive index difference between the core and the cladding. It can be derived from Snell's law. As a parameter determining the light-capturing efficiency, the numerical aperture, *NA*, is defined by the following equation:

$$NA = \sin \varphi_{max} = n_1 \sin \theta_c = (n_1^2 - n_2^2)^{1/2} \quad (1)$$

where n_1 and n_2 are the refractive indexes of the core and the cladding, respectively, φ_{max} is the maximum launching angle of the light, and θ_c is the critical angle for total internal reflection.

Optical fibers are generally classified into two types: multimode fibers and single-mode fibers (SMFs).

2.2. Multimode Fibers

Multimode fibers have a relatively large refractive index difference (typically 1 to 2 %) between the core and the cladding and a large core diameter, which is significantly larger than the wavelength of light and is typically several tens of micrometers or larger. Because of these structural parameters, the multimode fibers have many light paths (or modes) traveling through the core with slightly different angles.

The multimode fibers are further classified into two types depending on the refractive index profiles of the core: step-index fibers and graded-index fibers. Figure 2 illustrates those two types of multimode fibers. The core of the step-index fiber has a constant refractive index higher than that of the cladding, while the graded-index fiber has the refractive index gradually changing as a function of the radial position.

Figure 2. Classification of optical fibers according to propagation modes

(a) step-index fiber; (b) graded-index fiber; and (c) single-mode fiber. a) Core; b) Cladding; c) Refractive index, *n*

2.3. Single-mode Fibers

When both the core–cladding refractive index difference and the core diameter are reduced, the number of the transmitting modes (light paths) is decreased. Only one mode can be transmitted through the core, when these two parameters are sufficiently small. This is the case of the SMF as illustrated in Figure 2.

The basic type of silica-based SMF has a typical refractive index difference of 0.3 to 0.4 % and a core diameter of several µm. This standard type SMF is currently being used very widely in telecommunications. In optical communication systems using the standard SMFs, the optical signal wavelengths mostly used are 1.3 µm, at which the fibers have small or zero chromatic dispersion, and 1.55 µm, at which the fibers exhibit the lowest transmission loss, as described in detail in Section Characterisitics of Optical Fibers.

2.4. Dispersion-modified Fibers

Although the standard SMFs are superior transmission media for optical communication, even higher performance optical fibers of various types have been developed within the SMF category. The key parameter here is the chromatic dispersion. Since all silica-based fibers exhibit the lowest transmission loss around the 1.55-µm wavelength, this wavelength band is naturally suited for long-distance transmission. The chromatic dispersion of the standard SMF is, however, relatively large in the 1.55-µm band. This may limit the transmission capacity or the transmission distance. Various types of SMFs whose chromatic dispersion, especially in the 1.55-µm band, is modified or tailored to improve the transmission performance have been developed. These dispersion-modified fibers usually have somewhat complicated refractive index profiles as illustrated in Figure 3.

Figure 3. Refractive index profiles of dispersion-modified fibers and chromatic dispersion characteristics of various fibers

2.4.1. *Dispersion-shifted Fibers*

The dispersion-modified fibers of the first generation are dispersion-shifted fibers (DSFs) [13, 14]. The DSFs have their zero dispersion wavelengths (the wavelengths at which the chromatic dispersion is zero) shifted from the 1.3-µm band to the 1.55-µm band, where the transmission loss is minimized. The DSFs are well suited to long-distance transmission of high bit-rate optical signals.

2.4.2. *Nonzero Dispersion-shifted Fiber*

As the optical transmission technologies have recently been evolved with the advent of the optical fiber amplifier and wavelength-division-multiplexed (WDM) transmission, further modification of the chromatic dispersion characteristics has been applied to the DSFs. In long-distance WDM transmission with narrow wavelength spacing using optical amplifiers, the signal quality tends to deteriorate because of nonlinear effects in the optical fiber. Such detrimental effects become significant especially when the chromatic dispersion of the optical fiber is close to zero in the signal wavelength band.

The modified versions of DSFs whose chromatic dispersion is small but not zero in the 1.55-µm band are called nonzero dispersion-shifted fibers (NZ-DSFs) [15, 16]. The NZ-DSFs are being widely used in long-distance and large-capacity WDM transmission systems.

2.4.3. *Dispersion-flattened Fibers*

In general, the chromatic dispersion of the optical fiber has some dependence upon the wavelength. The wavelength dependence of the dispersion (the differential of the dispersion with respect to the wavelength) is called *dispersion slope*. Since both the DSFs and the NZ-DSFs have some dispersion slopes, the chromatic dispersion varies to some extent within the signal wavelength range. This dispersion variation is increased and may become undesirable when the signal wavelength band to be used is extended.

The SMFs whose dispersion slope is nearly zero in the wavelength range of concern are called dispersion-flattened fibers (DFFs) [17, 18]. Because precise control of such dispersion characteristics is generally difficult in view of the fiber design and fabrication, DFFs are still in the developmental stage and not yet fully commercialized.

2.5. Functional Fibers

Although optical fibers were originally developed as transmission media for optical signals, they have also found a number of applications in which their optical functionality, other than optical transmission, is utilized. Among these functional fibers are dispersion-compensating fibers (DCF), rare-earth-doped fibers, and polarization-maintaining fibers (PMFs).

2.5.1. *Dispersion-compensating Fibers*

When high bit-rate optical signals in the 1.55-µm band are transmitted through long standard SMFs, the signal waveforms are deformed because of the relatively large positive chromatic dispersion. This signal deterioration can be suppressed by inserting some SMFs that have large negative chromatic dispersions, which compensate for the positive dispersions of the transmission fibers [19]. These DCFs are typically coiled and packaged in small boxes. Such DCF modules are placed in the transmission equipment and used as optical functional devices.

2.5.2. *Rare-earth-doped Fibers*

Some of rare earth elements are known to be luminescent. Optical fibers whose cores are doped with specific rare earth elements function as optical amplifiers. One of the most important rare earth elements is erbium, which is capable of amplifying optical signals around the wavelength of 1.55 µm [20, 21]. The 1.55-µm band is one of the major wavelength bands used in optical fiber communication, because silica fibers exhibit the lowest transmission loss. Praseodymium and thulium are also known as additives for optical amplification in the 1.3-µm and 1.45-µm bands, respectively [21, 22].

Figure 4 illustrates the basic configuration of the erbium-doped fiber amplifier (EDFA). The pumping light at 0.98 µm or 1.48 µm launched into the fiber excites the erbium ions in the core, and the 1.55-µm optical signals traveling through the fiber are amplified through stimulated emission from the erbium ions. The EDFAs are not only highly efficient in terms of the signal gain or the output power but are also capable of simultaneously amplifying multiple optical signals that are WDM in the 1.55-µm band. This feature has strongly supported the recent dramatic progress of WDM transmission.

Figure 4. Basic configuration of an erbium-doped fiber amplifier

2.5.3. *Polarization-maintaining Fibers*

Single-mode optical fibers that maintain the linear polarization state of the light transmitted through the fibers are called polarization-maintaining fibers (PMFs). A typical cross section of the PMF is illustrated in Figure 5 [23]. The polarization of light is maintained by the birefringence that is induced by two stress-applying parts composed of SiO_2–B_2O_3 placed beside

the core. The PMFs are often used in optical fiber sensors, such as fiber-optic gyroscopes, or for interconnection between optical devices that have polarization dependence, such as laser diodes, optical modulators, and so on.

[Top of Page]

3. Raw Materials and Production

Optical fibers are basically made of optically transparent materials. Most of the optical fibers currently used in optical communication are silica-based fibers because of their low transmission loss. There are also several materials other than silica that are used for optical fibers, such as multicomponent glass, plastic, fluoride glass and so on.

3.1. Silica Fibers

Silica fibers are composed of SiO_2 and some additives that modify the refractive index of silica. The additives are essential for forming the basic fiber structure consisting of the core and the cladding, which have slightly different refractive indexes. The refractive index of silica can be decreased by adding fluorine or B_2O_3 and increased by adding other metal oxides or anions. The most popular additive or dopant for increasing the refractive index is GeO_2. P_2O_3 and Al_2O_3 are also known to increase the refractive index. Figure 6 shows the effects of various materials on the refractive index of silica.

Figure 6. Relationship between dopant concentration and refractive index of silica

3.1.1. *Preform Production*

In the production of silica fibers, silica-based glass rods, called preforms, are prepared first, and then the preforms are drawn into thin fibers. A vapor-phase method is generally used to form silica fiber preforms. There are four major preform fabrication techniques: modified chemical vapor deposition (MCVD), outside vapor deposition (OVD), vapor-phase axial deposition (VAD), and plasma chemical vapor deposition (PCVD).

In preform production by the MCVD and the PCVD methods, the following oxidation reaction is utilized to synthesize SiO_2:

$$SiCl_4 + O_2 \rightarrow SiO_2 + 2\,Cl_2$$

The following hydrolysis reaction is employed in the OVD and the VAD methods:

$$SiCl_4 + 2\,H_2O \rightarrow SiO_2 + 4\,HCl$$

The typical raw materials are volatile liquids (e.g., $SiCl_4$, $GeCl_4$, BBr_3, $POCl_3$) and gases (e.g., BCl_3, CCl_2F_2, SiF_4). Since the vapor pressures of transition-metal halides are much lower than those of the raw materials, the fibers fabricated using these techniques are very pure in terms of transition-metal impurities.

3.1.1.1. *Modified Chemical Vapor Deposition (MCVD) Method*

The MCVD technique, which was developed by Bell Laboratories [24], achieves glass deposition by letting the raw material vapors and oxygen flow through a rotating silica tube, as illustrated in Figure 7. The tube is heated by using a traversing O_2–H_2 burner. To obtain the desired refractive index profile, a number of glass layers of different compositions are deposited on the inner wall of the tube. In some cases, P_2O_5 is added to decrease the deposition temperature. After the deposition, the temperature is raised to 1800 to 2000 °C to collapse the tube into a solid preform.

Figure 7. Modified chemical vapor deposition (MCVD) method

(a) Deposition and (b) collapsing. a) Mass flow controller; b) Rotating silica tube; c) Synthetic glass layer; d) Traversing burner

3.1.1.2. *Outside Vapor Deposition (OVD) Method*

The OVD technique was developed by Corning Glass Works [8]. Figure 8 illustrates the principle of the OVD technique. Fine

glass particles (soot) are produced by flame hydrolysis of the raw materials with an O_2–H_2 burner and deposited on a rotating rod. A number of soot layers are deposited by moving the burner many times along the rotating rod. The vapor composition is changed layer by layer to produce a desired refractive index profile. After the deposition, the original rod is removed from the soot rod, which is then dehydrated by heating in chlorine gas and sintered to form a solid preform.

Figure 8. Outside vapor deposition (OVD) method

(a) Soot deposition and (b) consolidation. a) deposited soot; b) rotating rod; c) traversing burner; d) soot rod; e) heater

3.1.1.3. *Vapor-Phase Axial Deposition (VAD) Method*

The VAD technique was developed by several Japanese companies [25]. Soot generated by flame hydrolysis is deposited on the end of a rotating seed rod. A soot preform then grows in the axial direction, as illustrated in Figure 9. In the case of graded-index fiber preform production, the refractive index profile is determined by controlling the temperature distribution on the growing soot surface. Multiple O_2–H_2 burners may also be used to simultaneously deposit both the core and the cladding for step-index fiber preforms. The soot preform is then dehydrated by heating in chlorine gas, and finally sintered to form a solid preform.

Figure 9. Vapor-phase axial deposition (VAD) method

a) rotating seed rod; b) soot preform; c) O_2–H_2 burner; d) mass flow controller

Since the soot grows continuously in the axial direction in the VAD method, there is no fundamental limit to the soot length that can be fabricated. The VAD technique enables fabrication of very large preforms with high productivity.

3.1.1.4. *Plasma Chemical Vapor Deposition (PCVD) Method*

The PCVD technique was developed by Philips [26]. Its concept is illustrated in Figure 10. A silica tube is evacuated to reduce its internal pressure and raw materials and oxygen are fed in. Oxidation occurs in nonisothermal plasma produced by a microwave cavity. The tube is typically placed in a furnace whose temperature is raised to 1200 °C, for example. After the deposition, the tube is collapsed at a high temperature.

Figure 10. Plasma chemical vapor deposition (PCVD) method

a) Furnace; b) Traversing microwave cavity; c) Silica tube

3.1.2. ***Fiber Drawing***

Silica fibers are fabricated by heating the end of a preform in a furnace and drawing it, as shown in Figure 11. The drawing temperature is typically 2100 °C. There are two types of drawing furnaces: a carbon resistance furnace and a radio-frequency induction furnace. The fiber diameter (typically 125 µm) is precisely controlled during the drawing process by monitoring the diameter and adjusting the drawing speed.

Figure 11. Fiber drawing process

a) Preform; b) Furnace; c) Fiber diameter monitor; d) Coating applicator; e) Curing furnace; f) Capstan; g) Take-up bobbin

In order to maintain the mechanical strength of silica fibers, it is essential to immediately coat the fiber with some sort of resin before it comes in contact with rollers or take-up bobbins in the drawing process. This prevents the generation of microscopic cracks on the fiber surface. Figure 12 shows a comparison of the tensile strength between uncoated fibers and coated fibers. Typical coating materials are urethane acrylate and silicone. The former is cured by ultraviolet light, and the latter is usually cured by heat. A standard coating diameter is 250 µm.

Figure 12. Tensile strength of coated and noncoated fibers

3.2. Non-silica Fibers

3.2.1. *Multicomponent Glass Fibers*

Multicomponent glass fibers are fabricated from ultrapure powders such as SiO_2, Na_2CO_3, $CaCO_3$, and KNO_3. These powders are mixed and melted in a crucible to form homogeneous, bubble-free glass. The core and cladding glasses are melted separately, and then processed by the so-called double-crucible method, which employs two crucibles that have concentric orifices at the bottom. The core glass is placed in the center crucible and the cladding glass in the outer crucible. The crucibles are heated and the core and cladding glasses are drawn into a fiber having the core–cladding structure.

Although the multicomponent glass fibers are relatively easy to fabricate because of their low melting temperatures, their transmission losses are higher than silica fibers. The transmission loss is typically 5 dB km^{-1} at 0.85 µm [27].

3.2.2. *Plastic Cladding Fibers*

While the standard silica fibers have the core and the cladding both of which are composed of silica, the cladding can be replaced by some kind of polymer whose refractive index is lower than that of the silica core. This type of optical fiber is called plastic cladding fiber.

The plastic cladding fibers can be fabricated by using techniques very similar to those developed for silica fibers. The fiber is drawn from a silica rod and coated immediately with a low refractive index resin, such as silicone, as the cladding. The core can be either pure silica with a constant refractive index (the step-index fiber) or germanium-doped silica with a graded-index profile (the graded-index fiber).

3.2.3. *All-plastic Fibers*

All-plastic fibers consist of a plastic core and a plastic cladding. Polystyrene or polymethyl methacrylate is used as the core material and fluoropolymer as the cladding material, for example. The all-plastic fibers feature excellent flexibility and large dimensions (large core and cladding diameters), which enable easy connection and handling. Their transmission losses are, however, relatively high at wavelengths exceeding 0.6 µm because of C–H vibration absorption. Lower transmission losses at 1.3 µm have recently been achieved by using fluoropolymer as the core material [28]. Recent advances in fabrication techniques have also enabled the formation of graded-index profiles [29]. Graded-index all-plastic fibers featuring large bandwidths are believed to be useful for short-distance large-capacity transmission in buildings.

3.2.4. *Infrared Fibers*

As described in detail in Chapter Characterisitics of Optical Fibers, silica fibers have the lowest transmission loss around 1.55 µm, because of Rayleigh scattering, which is proportional to λ^{-4} and therefore decreases as the wavelength is increased, and the infrared vibration absorption by the Si —O bond in silica. It is anticipated that alternative materials having vibration absorption in much longer wavelength bands may exhibit a transmission loss lower than that of silica at wavelengths longer than 1.55 µm. Such non-silica materials that have been investigated are germanium dioxide, fluoride glasses, chalcogenide glasses, and crystalline halides [30, 31].

Figure 13 shows examples of the transmission loss spectra of those infrared fibers. It is clear that the infrared fibers realize transmission losses lower than those of silica fibers in wavelengths longer than 2 µm. Attempts to achieve ultralow loss (lower than the silica fiber's minimum loss around 1.55 µm) in the infrared region, however, have never been successful. The infrared fibers are used in short-distance applications with signal wavelengths longer than 2 µm, such as optical sensors.

4. Characterisitics of Optical Fibers

4.1. Transmission Loss

The transmission loss of the optical fiber represents a decrease in optical power per unit length. It is directly related to the maximum distance over which optical signals can be transmitted in optical communication systems, and is one of the most important parameters of the optical fiber. The transmission loss of the optical fiber is generally given by the following equation:

$$\alpha(\lambda) = \frac{A}{\lambda^4} + B + C(\lambda) \quad (2)$$

where

λ = wavelength of light (µm)

A = Rayleigh scattering coefficient (dB km^{-1} µm^{-4})

B = loss induced by structural imperfection (dB km^{-1})

$C(\lambda)$ = wavelength-dependent loss induced by impurities and intrinsic absorption (dB km^{-1})

A typical transmission loss spectrum of silica fiber is shown in Figure 14. The first term in Eq. (2) is Rayleigh scattering, which is caused by microscopic fluctuation of the density and/or the composition in glass, and it is one of the fundamental losses of glass. The Rayleigh scattering loss is proportional to λ^{-4}. The Rayleigh scattering coefficient, A, is approximately 0.7 dB km^{-1} µm^{-4} for pure silica, and it increases as the concentration of index-changing additives, such as GeO_2, is increased.

Figure 14. Typical transmission loss spectrum of silica fiber

The second term, the structural-imperfection-induced loss, is related to longitudinal fluctuation of the core – cladding interface, for example, and it is generally independent of the wavelength. Improvement of the fabrication techniques has reduced the structural-imperfection-induced loss to negligibly small levels.

One of the major contributions included in the third term of Eq. (2) is the intrinsic absorption induced by vibration of the Si —O bond in silica. A large absorption having a peak at 9.1 µm affects the transmission loss at wavelengths longer than 1.55 µm. Other important causes of absorption are hydroxyl bonds and transition-metal impurities, such as iron, copper, cobalt, or nickel. In general, the concentration of the transition metal is so small that it does not affect the transmission loss of silica fibers manufactured properly. On the other hand, the hydroxyl bonds exhibit a peaky absorption loss spectrum around 1.39 µm. However, it is also possible to reduce the hydroxyl content to sufficiently small levels by using improved dehydration techniques in preform production [32]. Optical fibers with no hydroxyl loss around 1.39 µm are now commercially available.

In the end, the fundamental loss causes in silica fibers are only Rayleigh scattering and the Si —O bond absorption. Since the Rayleigh scattering coefficient depends on the dopant concentration in the core, the lowest transmission loss can be achieved by a pure-silica-core fiber, which consists of a pure silica core with no additives and a cladding containing fluorine that lowers the refractive index. Sumitomo Electric has reported the lowest transmission loss record of 0.1484 dB km^{-1} [11], which is significantly lower than the standard germanium-doped-core fibers' loss of 0.2 dB km^{-1}.

4.2. Dispersion

The dispersion represents the variation in the group velocity of light transmitted through the optical fiber. In general, the dispersion determines the deformation of the optical signal waveforms, thus the transmission bandwidth of the optical fiber. The dispersion is classified into three categories: multimode dispersion, chromatic dispersion, and polarization mode dispersion.

4.2.1. *Multimode Dispersion*

The multimode dispersion is the variation in the group velocity among many different transmission modes, or many light rays traveling with slightly different angles through multimode fibers. The multimode dispersion is applicable only to multimode fibers. The concept of the multimode dispersion is shown in Figure 2.

The refractive index profiles of the graded-index fibers are designed so that almost all light paths have the same group velocity. Note that the apparently shortest light path traveling straight along the core axis does not necessarily have the highest velocity, since the velocity of light depends on the refractive index of the material (the higher the refractive index, the lower the velocity). The optimum refractive index profiles of the graded-index fibers, which minimize the group velocity variation among all transmission modes (light paths), are known to be nearly parabolic. The bandwidths of the step-index fibers are significantly smaller than those of the graded-index fibers because of the multimode dispersion.

4.2.2. *Chromatic Dispersion*

There is no multimode dispersion in SMFs, since they have only one transmission mode. Therefore, SMFs, in general, exhibit much larger transmission bandwidths than multimode fibers. The dispersion characteristics of SMFs are determined by the chromatic dispersion and the polarization mode dispersion.

Figure 15 schematically shows the chromatic dispersion. The chromatic dispersion is the differential of the group delay of light transmitted through the optical fiber with respect to the wavelength. The chromatic dispersion can be divided into two effects: material dispersion and waveguide dispersion. The material dispersion is the characteristic intrinsic to the material, silica in this case, and it varies depending upon the additives, such as germanium, but not very much. On the other hand, the waveguide dispersion is the dispersion induced by the fiber structure, and it strongly depends on the refractive index profile. By properly designing the refractive index profile, it is possible to some degree to tailor the waveguide dispersion, and thus the chromatic dispersion. This is the base of the various dispersion-modified fibers described in Chapter Structure of Optical

Fibers.

Figure 15. Group delay and chromatic dispersion characteristics of optical fibers

4.2.3. *Polarization Mode Dispersion*

Actually, SMF has two transmission modes, both of which are basically the same but whose polarization axes are perpendicular to each other. The polarization mode dispersion (PMD) is the group delay difference between those two orthogonal polarization modes. If the optical fiber is perfectly circular, the polarization modes have the same group velocity, but slight noncircularity of the fiber structure and/or asymmetric stress distribution applied to the fiber induce some birefringence, thus the PMD. Because optical power transfer between the two modes randomly occurs during transmission through the fiber, behavior of the PMD has a somewhat statistical nature. The PMD is generally proportional to the square root of the fiber length.

4.3. Nonlinearity

In general, phenomena whereby the material properties of a given medium change when high-intensity light is transmitted through it are called *nonlinear effects* (see ⟶ Nonlinear Optics and [33]). The nonlinearity of silica is significantly small compared with various other glasses. It has, however, become important recently because optical fiber amplifiers increase the optical signal power and the number of multiplexed optical signals in the optical fiber, resulting in noticeable levels of nonlinear effects even in silica fibers.

The nonlinear effects that are of most concern for optical fibers are nonlinear refractive index (optical Kerr effect) and stimulated scattering. The nonlinear refractive index is a small variation of the refractive index dependent upon the light intensity. This may cause various detrimental effects in the optical fiber communication, such as self-phase modulation, cross-phase modulation, and four-wave mixing. Among the stimulated scattering phenomena are stimulated Raman scattering and stimulated Brillouin scattering. While nonlinear effects are generally harmful in optical fiber communication, they are also useful in a variety of applications, such as fiber Raman amplifiers.

[Top of Page]

5. Reliability of Optical Fibers

5.1. Mechanical Strength

The mechanical lifetime of the optical fiber depends on the stress applied to the fiber and the environmental conditions [34]. Figure 16 shows the relationship between the average time to fiber breakage and the applied stress in air and water. The time to fiber breakage or the time to failure, t_f, is given by

$$\ln t_f = -n \ln \sigma_a + \ln k_s \tag{3}$$

where σ_a is the applied stress, and n and k_s are constants that depend on the glass material and the environmental conditions. For silica fibers in air, n is approximately 25 and k_s about 2.2×10^{12}. In production of the optical fiber, a certain level of stress is applied to the fiber after drawing in order to eliminate any weak portion; this is called *proof testing*. The expected lifetime of the fiber, t_{min}, is given by

$$\ln t_{min} = n \ln \sigma_a + \ln \left(B\sigma_p^{n-2}\right) \tag{4}$$

where σ_p is the stress applied during the proof testing and σ_a is the stress applied to the fiber in use, for example, the fiber in a cable. The constant B depends on the glass material and the environmental conditions. In general, high humidity and high temperature shorten the fiber lifetime. However, proper proof testing in the fiber production and appropriate cable designs ensure long-term reliability in standard applications.

Figure 16. Relationship between time to failure and applied stress for silica fibers in air and water

5.2. Hydrogen-induced Loss Increase

Hydrogen may be produced in optical fiber cables as a result of thermal dissociation of plastic, corrosion of metal by water, or

electrolysis of water when two different metals are used in a cable. Two types of loss increase due to hydrogen are known: absorption by hydrogen gas permeated into the glass and absorption by hydroxyl bonds formed as a result of reactions between the glass and the hydrogen gas [35, 36]. The former loss increase is reversible, while the latter is not. Figure 17 shows the loss spectra of an optical fiber before and after 36-week exposure to hydrogen gas at room temperature. The permeated hydrogen causes absorption of 8 dB km^{-1} at 1.24 µm.

Figure 17. Transmission loss spectra of a silica fiber before and after 36-week exposure to hydrogen at room temperature

Figure 18 shows the loss spectra of two SMFs before and after exposure to hydrogen at 200 °C. At high temperatures, the hydroxyl absorption having a peak at 1.39 µm increases in the standard germanium-doped-core fiber, while the pure-silica-core fiber exhibits no loss increase. This is because GeO_2 reacts with hydrogen to form hydroxyl bonds but pure silica does not. The pure-silica-core fiber is superior in terms of the transmission loss stability against hydrogen.

Figure 18. Stability of optical fibers after heating in hydrogen at 200 °C

(a) Single-mode fiber with a pure silica core; and (b) single-mode fiber with a GeO_2-doped silica core

5.3. Radiation-induced Loss Increase

The transmission loss is also increased by irradiation [37]. The loss increase depends upon the type of radiation, its intensity (dose rate), the composition of the fiber, the fiber fabrication process, and the fiber temperature during irradiation. The effects of ϒ-ray, X ray, ultraviolet light, or neutron irradiation have been examined.

Among various silica-based fibers, the pure-silica-core fiber exhibits the smallest loss increase after irradiation. Addition of GeO_2 or P_2O_5 to silica results in a high sensitivity to all forms of irradiation, while B_2O_3 specifically increases the sensitivity to neutron irradiation. The sensitivity is reduced by adding hydroxide ions or hydrogen and is increased by adding chlorine.

For a given total radiation dosage, the transmission loss increase is much larger for higher dose rates. In addition, irradiation at a higher temperature results in a smaller loss increase and faster recovery of the radiation-induced loss. Visible or infrared light irradiation also helps to suppress the loss increase and accelerate the loss recovery; this phenomenon is called *photobleaching* [38].

[Top of Page]

6. Applications of Optical Fibers

6.1. Optical Fiber Cables

Optical fibers are used most typically in the form of optical fiber cables. Optical fiber cables are generally thinner and lighter than conventional communication cables, such as copper wire cables or coaxial cables. Optical fiber cables are free from any influence from electromagnetic induction; this is another advantage over conventional copper cables. Optical fiber cables have a wide variety of applications, such as long haul or metropolitan telecommunication networks, submarine cable networks, local area networks, broadband access (fiber to the home) networks, and so on. There are also various composite type cables, which contain optical fibers for addition of the communication function. Examples of such composite cables are electric power/optical fiber composite cables and optical ground wires (OPGW).

Figure 19 illustrates the cross sections of three major optical fiber cable types used in telecommunications: the loose tube type cable, the slotted-core type cable, and the single tube type cable. Optical fiber cables are designed so that the optical fibers inside are free from excessive strain or bending during and after installation. In loose tube type cables, optical fibers are loosely encased in plastic tubes, and the tubes are stranded around a central strength member. In the case of slotted-core type cables, a number of individual fibers or fiber ribbons (fiber arrays formed with some resin) are placed in each slot or groove, which is helically formed on the surface of a central rod having a strength member. Single tube type cables contain individual fibers or fiber ribbons in the central tube. In any case, proper design of the cable structure ensures stable performance of optical fibers.

Figure 19. Examples of optical fiber cables

(a) Loose tube type cable; (b) Slotted-core type cable; and (c) Single tube type cable

6.2. Fiber Connection Technologies

It is highly important to connect optical fibers in various situations. The loss of the optical signal at the connection should be as small as possible. Since the core of the optical fiber is very small, precise alignment of the ends of two optical fibers to be connected is key. There are three types of fiber connecting technologies: fusion splicing, optical connectors, and mechanical splicing.

Figure 20 illustrates the principle of fusion splicing. Fiber ends are melted by means of a high-frequency electric discharge and permanently joined. Prior to fusion splicing, perfectly flat fiber ends are prepared by utilizing fiber-cleaving tools. In the case of the optical connector, the ends of the optical fibers are inserted and fixed in high-precision ferrules, which are then mated by using an alignment sleeve, as illustrated in Figure 21. In fabrication of the optical connectors, the end faces must be polished flat. The optical connectors can be connected and disconnected repeatedly. Multifiber connectors, which simultaneously connect multiple fibers or fiber ribbons with the fiber count of 4, 8, or more, have also been developed and put to practical use.

Figure 20. Principle of fusion splicing

a) Optical fiber; b) Electrode; c) V-groove; d) Fiber coating

Figure 21. Principle of an optical fiber connector

a) Optical fiber; b) Ferrule; c) Alignment sleeve

Mechanical splicing is a technique for semipermanent fiber connection that utilizes relatively simple tools, unlike fusion-splicing machines. The optical fiber ends are prepared by using the fiber-cleaving tool and then connected by utilizing high-precision fiber aligning parts. In general, the connection loss is lowest for fusion splicing, and relatively high with optical connectors and mechanical splicing.

6.3. Optical Fiber Sensors

A variety of sensors that utilize optical fibers have been developed, and some of them have already been brought into practical use. Examples of such optical sensors are fiber-optic gyroscopes and fiber-optic temperature distribution sensors.

The fiber-optic gyroscopes utilize a phenomenon called the *Sagnac effect*, in which light traveling clockwise and light traveling counterclockwise in the same optical fiber coil experience slightly different phase shifts when the optical fiber coil is rotating. Since the phase difference depends on the angular velocity of the coil, the rotation can be detected by observing the phase difference. Ultrahigh sensitivity can be realized by properly designed fiber-optic gyroscopes.

Fiber-optic temperature distribution sensors utilize the Raman scattering effect, which is one of the nonlinear effects in optical fibers. Since the amount of light generated by the Raman scattering effects in the optical fiber depends upon the temperature of the fiber, it is possible to determine the fiber temperature by observing the Raman scattering–induced light signals. By further examining the signals as a function of the location along the fiber, the temperature distribution along the fiber can be observed. Fiber-optic temperature distribution sensors are actually being used, for example, for monitoring the temperature distribution along electric power cables (which contain optical fibers as sensors).

[Top of Page]

7. Future Prospects

In the ubiquitous communications era, the transmission and exchange of huge amounts of data will be indispensable. As described in the previous chapters, various technologies have been developed to increase data transmission rates, such as Time Division Multiplexing (TDM) and Wavelength Division Multiplexing (WDM).

7.1. New Fibers

At present, dispersion-controlled silica fibers are developed for long-distance communication with TDM and/or WDM systems to achieve maximum transmission speed. Also, several types of transmission along new types of optical fiber have been proposed. These fibers are briefly described below.

7.1.1. *Photonic Crystal Fiber (PCF)*

In 1995, BIRKS et al. reported on Photonic Crystal Fiber (PCF) and Holey Fiber (HF), a type of PCF, and thereafter these types of fibers have been actively investigated [39]. PCF is manufactured by stacking an array of silica capillary rods to form a macroscopic preform and then by drawing it into fiber. Typically, PCF is made from hexagonal lattice of circular air columns in which the periodicity is relatively uniform.

Photonic Band Gap (PBG) is defined as the range of frequency and propagation constant of light in which light is prohibited to propagate. It appears by arranging air holes in silica glass adequately.

7.1.2. *Holey Fiber (HF)*

HF has a periodic lattice of air holes distributed in the oblique section so as to form a core-clad microstructure that enables total reflection.

Owing to the large refractive index contrast that exists between glass and air, HF has unique properties, such as very high nonlinearity, a small effective core area, an enormous amount of waveguide dispersion that can be used for compensating the large material dispersion of silica, and so on [40].

7.1.3. *Photonic Band-gap Fiber (PBGF)*

CREGAN et al. demonstrated in 1999 that light can be strictly guided without leakage along a hollow core [41]. Light in certain well-defined wavelength bands is trapped in air by a full two-dimensional photonic band gap. PBGF is expected to greatly reduce Rayleigh scattering and nonlinearity. It also may hold the promise of yet undiscovered properties that are not attainable in standard fibers.

Recently, ultrashort pulse lasers such as femtosecond and picosecond pulse lasers have been developed. With ultrashort pulses, the wavelength spectrum can be very broadly spread. However, there are no fibers that can cover such a wide spectrum. Therefore, new types of fiber that use new materials or an air containing structure with a wider wavelength region will be required.

7.2. New Systems

As far as using ordinary optical fiber bit rate and distance of repeater spacing are inevitably limited owing to dispersion of optical fiber, that is, wavelength dependency of group velocity. In order to cope with these limitations, optical soliton transmission utilizing the nonlinear optics effect and Code Division Multiplex (CDM) have been proposed as new breakthrough technologies.

7.2.1. *Soliton System*

In 1973, HASEGAWA and TAPPERT proposed that soliton waves could be applied to optical fiber communications [42]. The pulse, a soliton wave, is generated when the group velocity dispersion of glass fiber and the tertiary nonlinear optical effect called self-phase modulation effect are balanced.

The self-phase modulation effect appears when the power level of optical pulse is increased and the nonlinear optical effect accordingly becomes larger. An equilibrium condition occurs and very long-distance repeater spacing is possible thanks to the absence of distortion.

This proposition has been verified through laboratory testing. However, no practical soliton system has yet been deployed, because power level control has not yet reached a sufficient level of sophistication.

7.2.2. *Code Division Multiplex (CDM)*

With very high-speed digital transmission, all-photonic switching will be required because electronic switching cannot function at such high speed. Therefore, new components including fiber for all-photonic switching, such as two-dimensional space modulation, will be required.

The extension of today's TDM and WDM technologies will have limitations because of nonlinearity, polarization, and the temperature dependency of fiber. Therefore, new modulation systems, such as CDM using a concept like spread spectrum [43], will be required in the future.

Glossary

MCVD

Modified chemical vapor deposition, one of the silica optical fiber fabrication methods developed by Bell Laboratories. The deposition of the core and the cladding layer is achieved by passing the oxygen and the raw material vapors, that is, $SiCl_4$ and $GeCl_4$, through a rotating heated silica tube. After deposition, the temperature is increased to collapse the tube into a solid preform. The preform is drawn into fiber by heating it in a drawing furnace.

Optical Communication System

The combination of a light source that converts electrical signals to light signals, an optical fiber that is a transmission medium for the optical signals, and a detector that reconverts the optical signals to electrical signals. It is a low-cost system because of the long repeater spacing and high transmission capacity compared to a conventional telecommunication system.

Optical Fiber

A transmission medium for optical communications systems made with transparent materials, i.e, glass or plastic. It consists of a core surrounded by a cladding layer that has a lower refractive index than the core material. An optical

signal is transmitted in the core by total internal reflection.

OVD

Outside vapor deposition, one of the silica optical fiber fabrication methods developed by Corning Glass Works. Fine glass particles produced by flame hydrolysis of the raw materials, i.e, $SiCl_4$ and $GeCl_4$, with a $C_2H_6O_2$ burner are deposited on the lateral surface of a rotating rod. After deposition, the rod is removed from the soot boule, which is then dehydrated by heating in chlorine gas and sintered to a transparent preform. The preform is drawn into fiber by heating it in a drawing furnace.

PCVD

Plasma chemical vapor deposition, one of the optical fiber fabrication methods developed by Philips. The oxygen and the raw material vapors, that is, $SiCl_4$ and $GeCl_4$, pass through a rotating heated silica tube, which is evacuated. In the silica tube, oxidation of the raw materials occurs in a plasma, and core and cladding glass layers are deposited on the inner surface of the tube. After deposition, the temperature is increased to collapse the tube into a solid preform. The preform is drawn into fiber by heating it in a drawing furnace.

VAD

Vapor-phase axial deposition, one of the silica optical fiber fabrication methods developed by Japanese companies. Fine glass particles produced by flame hydrolysis of the raw materials, that is, $SiCl_4$ and $GeCl_4$, with an O_2–H_2 burner are deposited on one end of a rotating seed rod. A soot preform then grows along the axis of the rod. The core and the cladding soots are deposited simultaneously. After that, it is dehydrated by heating in chlorine gas and sintered to transparent preform. The preform is drawn into fiber by heating it in a drawing furnace.

1. Introduction

The term fibers refers collectively to a wide variety of forms of fibrous materials. Standards have been established to introduce order into the field. The most frequently employed terms are defined here. Natural fibers that can be spun into yarn are called *staple fibers.* The primary spinning of man-made fibers results in the production of *continuous filaments* (endless fibers). Indeed, both *monofilaments* (threads; spinneret has one hole) and *multifilaments* (spinneret has many holes) can be produced. *A filament yarn* consists of a large number of filaments that can be given texture by twisting, crimping and/or heat setting.

The word *tow* refers to a *fiber tape* made from thousands of filaments. If a tow is cut or torn, it gives rise to staple fibers. Fiber tapes obtained by cutting or tearing parallel to the fibers are known as *fiber bands.*

Conventional standards divide fibers into (1) *natural fibers* and (2) *man-made fibers* (also called chemical fibers).

Natural fibers are subdivided into plant and animal fibers. Man-made fibers are subdivided into natural materials brought into fiber form by a chemical reaction (regenerate fibers) and fibers made from synthetic polymers (synthetic fibers). The following classification includes standardized abbreviations that are used occasionally throughout this article:

1. Natural fibers
1.1. Plant fibers, e.g.,
cotton
flax
hemp
jute
1.2. Animal fibers, e.g.,
wool
camel hair
angora
silk
2. Man-made fibers
2.1. Fibers based on natural polymers, e.g.,
viscose rayon (CV)
Lyocell (CLY)
cellulose acetate (CA)
elastodiene (LA)
2.2. Fibers based on synthetic polymers (synthetic fibers), e.g.,
polypropylene (PP)

polyacrylonitrile (PAN)
poly(vinyl chloride) (PVC),
polyamide 6 (PA 6, nylon 6)
polyamide 66 (PA 6,6; nylon 66)
poly(ethylene terephthalate) (PET)
poly(ether ether ketone) (PEEK)
polyurethane (PUR; spandex)

2. History

Natural Fibers. Natural fibers have been used by humans for thousands of years. Animal hair and plant fibers were spun into yarn and woven into textiles. Indeed, the textile industry today is still based on this ancient technology.

Man-Made Fibers. The idea of making "artificial" fibers and threads is over 300 years old. In fact, the start of the chemical fiber industry dates from about 1884. The process of regenerating fiber-forming cellulose was based on the discovery of solvents such as copper oxide – ammonia by E. Schweizer in 1857. Later, Count Chardonnet succeeded in forming derivatives of cellulose which could be solubilized and spun into threads; "Chardonnet silk" was first made in 1884. A detailed account of the history of man-made fibers is not given in this article. The subject was dealt with competently by H. Klare in 1985 [19].

The most important developments in the production of man-made fibers based on cellulose were:

1) the cuprammonium process for solubilization and spinning of cellulose;
2) the formation of spinning solutions of cellulose derivatives, such as cellulose nitrate and cellulose acetate;
3) the intermediate derivatization of cellulose to cellulose xanthate which in turn is spun into cellulose fibers;
4) the development of new solvent systems for cellulose, such as *N*-methylmorpholine oxide (NMMO) or dimethylacetamide – lithium chloride.

In 1927, H. Staudinger used polyoxymethylene as a model of cellulose to demonstrate that fiber-forming polymers were linear polymeric molecules.

The production of synthetic fibers was the result of pioneering work on the formation of synthetic polymers and the development of extrusion techniques known as wet, dry, and melt spinning.

Nylon 66 was first synthesized by W. H. Carothers in 1935. This was closely followed by the discovery of nylon 6 by P. Schlack in 1938. The work of J. R. Whinfield and I. T. Dickson led to the development of polyester fibers in 1941. Today, polyamides and polyesters are the largest-volume polymers capable of being melt-spun. The production of synthetic fibers based on familiar polymers such as polyacrylonitrile, which cannot be melt-spun, was made possible by the introduction of new solvents, e.g., dimethylformamide (H. Rein, 1942). Discovery of the stereospecific polymerization of propylene (G. Natta, 1954) led to the introduction of polyolefins into the fiber industry. The development of technology and the simultaneous elucidation of structure and properties resulted in "tailor-made" polymers and fibers. Specific properties such as rubber elasticity (O. Bayer, 1947) or extreme tenacity and stiffness were realized (high-modulus fibers, P. W. Morgan and S. L. Kwolek, 1968). In addition, high-temperature fibers were made from polyheterocyclic compounds.

Apart from organic polymers, inorganic substances such as glass, carbon, BN, and SiC were also spun into fibers.

Future developments are likely to be directed toward classical mass production, particularly towards the attaining of optimal processing characteristics and clothing comfort. New types of application – above all in the field of industrial fibers and in medical technology – will stimulate the development of special fibers with very specific properties.

3. Characteristics of Fibers

3.1. Fineness

The thickness of fibers and filaments ranges from 1 to 100 μm. Measuring thickness by means of conventional instruments is very difficult. Indeed, even small variations in fiber uniformity, thickness, and cross-sectional area hinder microscopic measurement. To make a sta-

tistically valid statement about the fineness of a fiber (fiber density), length and mass are computed instead of thickness. The unit *tex* is used to express fiber fineness. According to the ISO,

$$1\,\mathrm{tex} = 1\,\mathrm{g\,per\,1000\,m}$$

If 1000 m of fiber weigh 1 g, the fineness is 1 tex. Another unit commonly used to express fineness is dtex. If the mass per length is given in dtex, the numerical values will be comparable to those in the formerly used unit *denier* [46]:

$$1\,\mathrm{denier} = 1\,\mathrm{g\,per\,9000\,m}$$

3.2. Tenacity and Modulus of Elasticity

The cross-sectional area of fibers is generally nonuniform and cannot be determined easily. Hence, measurements based on area have limited applicability. For this reason, tenacity is not measured in gigapascal (GPa) units (ISO) but is expressed relative to the fineness. Usually, the maximal tensile force (at break) is employed, expressed in centinewtons per tex (cN/tex); other units used are cN/dtex (1 cN/dtex = 10 cN/tex) or N/tex (1 N/tex = 100 cN/tex). Textile and industrial fibers have tenacities ranging from 10 to more than 300 cN/tex (see Table 4). The modulus of elasticity corresponds to the tangent to the stress – strain curve at the origin (→ Fibers, 6. Testing and Analysis, Chap. 3.). It is also expressed relative to the fineness, in cN/tex. Typical moduli range from 50 to 1000 cN/tex for textile fibers and from 1000 to 40 000 cN/tex for industrial fibers. (See Table 5.)

3.3. Elongation

The highest possible degree of elongation at break (→ Fibers, 6. Testing and Analysis, Chap. 3.) varies greatly with the type of fiber. Industrial fibers, e.g., carbon fibers and high-modulus aramids, have values of 0.1 – 2 %; textile fibers and yarns have values of 5 – 70 %; and values of 300 – 700 % are obtained for spandex fibers (see Table 4).

In practical applications, fibers are elongated only to a small extent. Maximal elongation is never attained because otherwise fibers undergo partially irreversible stretching.

Temperature and moisture (weather) affect both the tenacity and the elongation of fibers to varying extents, depending on the type of polymer. The same applies to dimensional stability and wrinkling tendency, properties that are also influenced by the type of fiber and by the textile structure.

4. Spinning

Both natural and synthetic fibers are consisting of linear polymers. These polymers are converted into fibrous form by growth (animal hair, plant fibers) or extrusion (spider, silkworm, spinning technology) and are specifically oriented to the fiber axis. The many mechanisms found in nature for the formation of filamentous structures are, by no means completely understood (see e.g. [87]). Only a few processes are available for large-scale production of man-made fibers. Specific production techniques are based on the deformability of fiber polymers. In principle, a distinction is made between spinning methods involving solutions and those involving molten polymer. For a detailed description of spinning, see → Fibers, 3. General Production Technology.

4.1. Wet Spinning

Polymer solutions are converted into fibers by diluting a highly concentrated polymer solution in a coagulating bath. The extremely viscous polymer solution, e.g., 3.5 – 10 Pa · s (still higher values are obtained with viscose rayon) can be extruded, i.e., spun, by forcing it through a spinneret to form threadlike structures. In general, polymers are soluble only in specific solvents. The viscous polymer solution is extruded into a coagulating bath where the solvent is diluted, which results in precipitation of polymer threads. For instance, polyacrylonitrile is soluble in dimethylformamide (DMF). In the coagulating bath, DMF is washed out of the viscous polymer threads with water, and polyacrylonitrile fibers precipitate (Fig. 1).

Figure 1. Fiber formation by solvent extraction in the spinning bath
PAN = polyacrylonitrile: DMF = dimethylformamide

The solvent concentration in the fiber decreases along the length of the coagulating bath. In wet spinning, several physicochemical processes occur simultaneously, e.g., solvent diffusion, polymer precipitation, and formation of membrane-like interfaces and system-specific morphological structures. One of the main purposes of developing wet-spun polymers is to produce specific fiber structures in the coagulating bath. This is achieved, in principle, by modification in the coagulating bath, which is described in more detail under → Fibers, 4. Synthetic Organic, Chap. 5.3.3., wet spinning of polyacrylonitrile. In a spinning process of this type, the polymer can also undergo a chemical reaction; e.g., the viscose process involves acid hydrolysis of cellulose xanthate in the coagulating bath (→ Cellulose, Chap. 3.1.3.).

To make the process economical, the polymer concentration should be kept as high as possible during spinning. In the case of soluble polymers, the viscosity of the spinning solution, and thus its basic spinnability, are directly related to the concentration and solvation of the polymers. However, complicated processes, such as exchange, diffusion, and drying, that occur during wet and dry spinning result in polymer- and solvent-dependent limitations on the polymer concentration.

4.2. Dry Spinning

In dry spinning, the polymer solution is also forced through a spinneret. Solvent is then evaporated in a warm current of air to produce almost solvent-free filaments. Cellulose acetate, polyacrylonitrile, and polyurethane are spun by this technique (→ Cellulose Esters, → Fibers, 4. Synthetic Organic).

4.3. Melt Spinning

In melt spinning, the polymer is melted by heating and then passed through a spinneret via a spinning pump. Only polymers that are thermally stable under melt conditions can be subjected to this extrusion (i.e., spinning) process. The fluid threads emerging from the spinneret solidify on cooling (usually air cooling) to form filaments. This technique is applied in spinning, e.g., nylon 6, nylon 66, or poly(ethylene terephthalate) (→ Fibers, 4. Synthetic Organic).

The difference between melting and spinning temperatures depends on the viscosity of the melt. Usually, the spinning temperature is about 30 K higher than the melting temperature T_m. However, if the viscosity is still too high, the spinning temperature must be increased even further. For example, T_m of polypropylene is 170 °C but the polymer is spun at 260 °C. The melt index, not the viscosity, is generally used to characterize the melting properties of polymers. In fact, the tedious measurement of melt viscosity has now been replaced by simple mass determination (→ Fibers, 6. Testing and Analysis).

Hence, melt spinning requires polymers that are thermally stable and, as far as possible, resistant to thermal oxidation at temperatures approximately 30 K higher than their melting temperatures (PA-6, PA-66, and PET).

Production conditions must be optimally coordinated with the properties of the product to achieve the desired melt viscosity, on the one hand, and the required fiber tenacity, on the other. Rapid advances in process technology, however, have made possible not only the processing of very highly viscous melts, but also the extrusion of solids.

5. Prerequisites for Fiber Formation

5.1. Molecular Mass and Fiber Formation

The spinnability of polymer melts or solutions depends on their viscosity at technically feasible spinning conditions. The viscosity η of linear polymers depends, in turn, on the molecular mass M_r:

Table 1. Polymer type and molecular mass suitable for fiber formation

Polymer	Repeating unit	Fiber formation at M_r	Degree of polymerization
Polyethylene	$-CH_2-CH_2-$	> 1 000 000	> 62 500
Polypropylene	$-CH(CH_3)-CH_2-$	> 1 000 000	> 45 455
Polyacrylonitrile	$-CH(C\equiv N)-CH_2-$	> 30 000 – 70 000	> 1070 – 2500
Aliphatic polyamides	$-CH_2-NH-CO-CH_2-$	15 000 – 30 000	380 – 770
Aliphatic polyesters	$-CH_2-O-CO-CH_2-$	50 000	1300
Aliphatic–aromatic polyesters	$-O-CH_2-CH_2-O-CO-C_6H_4-CO-$	22 000 – 26 000	220 – 260
Aromatic polyamides	$-NH-C_6H_4-NH-CO-C_6H_4-CO-$	60 000	550

$$\eta = K \cdot M_r^{\alpha}$$

where K is a constant that is known for most common polymers.

The fiber-forming tendency of a polymer increases with increasing molecular mass. The varying forces of interaction between individual structural groups of polymers are directly related to the chemical nature of these linear molecules. For this reason, optimal conditions for fiber formation are very polymer-specific. In principle, the weaker the interaction between structural segments, the higher is the molecular mass required (Table 1) [47].

5.2. Molecular Structure and Fiber Properties

The thermochemical and photochemical stability of a fiber polymer is controlled by its chemical structure. The possibility of chemically modifying textile properties is determined by the chemical reactivity and polarity of the individual structural units (Table 2). The type of chemical bonds and the stereochemistry are important for molecular geometry, interaction of structural units, and thermal conformational stability. Low conformational mobility is generally related to high mechanical tenacity, modulus, and torsion modulus. Finally, the molecular organization is influenced by the symmetry of the structural units and of the entire molecular chain. The interaction energy (cohesion energy) controls the solubility and compatibility of structural units with each other. These factors finally lead to specific morphological domains, which frequently occur in block structures of varying chemical composition along the polymer chain, e.g., in polyurethane (spandex) fibers. The general relationship between the structure and properties of polymers suitable for fiber production is discussed in the literature [47]. In this section the structural elements of technically important fibers are compared.

Table 2. Structural characteristics of polymers and their importance for fiber properties

Structural characteristics	Importance for fiber properties
Chemical structure (primary structure)	thermochemical and photochemical stability, textile chemical processes (dyeing, textile finishing)
Molecular organization and symmetry	general properties, melting point, shrinkage behavior
Type of binding and stereochemistry (secondary structure)	thermophysical and thermomechanical properties (moduli, elasticity)
Conformation and conformational mobility	
Morphological structures, superstructures	diffusion (dyeing), breaking mechanism

Crystallization. The interaction between structural units is of considerable importance for crystallization. The chemical structure, stereochemistry, and symmetry of polymers determine, to a large extent, the structural conforma-

tion of the polymer under prevailing conditions such as temperature (melt or solid), condition of solution (solvation of molecules), coil structure, and aggregation. Higher orientation or parallelism of the chain molecules increases orientation of the structure elements. Their interaction also depends on the possible molecular conformations.

During spinning, a preliminary orientation of the molecules occurs, which is enhanced during drawing, and stabilized by partial crystallization. The individual segments usually crystallize independently of each other; hence amorphous intercrystalline areas exist unavoidably. The course of polymer crystallization, especially of fibers, is quite different from the crystallization characteristics of low molecular mass compounds.

5.3. Property Requirements for the Formation of Fiber Structures

Fiber-forming polymers require certain properties that make possible the formation of typical fiber structures; these are linearity, intermolecular forces, and the possibility of crystallization whereby, in general, supermolecular structures result.

1) *Linearity.* Only linear polymers can be expected to have optimal fiber-forming properties. Linearity is specifically a prerequisite for the spinnability of polymer solutions and melts.
2) *Intermolecular Forces.* After orientation of linear polymers during spinning and drawing, dispersion forces, e.g., dipole-dipole interactions or hydrogen bonds between the polymer segments contribute to the fixation of the polymer chains.
3) *Crystallization.* The well-developed organization of the polymer chains usually results in crystallization. Polymer-specific crystallization results in crystalline domains and amorphous intercrystalline areas.
4) *Supermolecular Structure.* The crystallites are oriented so that they lie parallel to the fiber axis, which results in supermolecular structures, e.g., fibrils and fibril bundles (→ Fibers, 2. Structure).

These requirements were fulfilled by STAUDINGER's model of cellulose as polymeric formaldehyde [48]. Even this simple compound met all the conditions for fiber formation. It is a meltable linear polymer, capable of crystallization with formation of fiber fibrils.

The simplest model for intermolecular dispersion forces (van der Waals forces) is shown in a polyolefin molecule such as polyethylene or polypropylene:

In poly(ethylene terephthalate), interaction between the aromatic π-electron systems of the benzene rings and of the carbonyl groups makes dipole – dipole interaction possible:

Hydrogen bonds act on amide or urea groups in polyamides, such as nylon 66 or nylon 6, or in polyurethane, respectively:

The OH groups of poly(vinyl alcohol) and of cellulose (viscose rayon) are also able to form hydrogen bonds. Very strong dipole – dipole interaction occurs between the nitrile groups of polyacrylonitrile:

However, this all-trans conformation of polyacrylonitrile can change into lower energy helical structures [49]:

The strong dipole–dipole interaction of polyacrylonitrile is one of the reasons for the specific solubility behavior of that polymer.

Weak dispersion forces are effective only in a highly symmetrical conformation. This high degree of symmetry, in turn, is possible only with a highly symmetrical arrangement of substituents, e.g., along an aliphatic carbon chain. Such a high degree of symmetry in linear polymers can be achieved only by coordination polymerization, in the presence of organometallic catalysts (Ziegler – Natta), to yield isotactic polymers. If this symmetry (e.g., in polypropylene) is disturbed by the presence of other structural units (e.g., carboxylic acid ester groups; acrylic acid comonomers), both polymer and fiber properties change drastically.

5.4. Crystallization

The flexible linear polymer takes on a variety of conformations during fiber formation, seeking the conformation with the lowest free energy (i.e., highest molecular organization). However, spinning conditions do not allow polymers to attain this state completely, and fiber polymers usually undergo only partial crystallization. The ratio of crystalline to amorphous regions varies from almost totally amorphous to highly crystalline, single-phase systems (Fibers, 2. Structure).

Linear polymers exist in solution or as molten polymer in a more or less coiled form (Fig. 2 A). In the shearing field during spinning, the molecules are partially uncoiled and oriented in the direction of flow (Fig. 2 B). A higher degree of orientation is achieved during the subsequent drawing operation (Fig. 2 C). In this step, spun fibers are stretched by more than 200 %, resulting in partial crystallization of polymer molecules (Fig. 2 D). In high-speed spinning, the extremely high windup speeds (3000 – 6000 m/min; 50 – 100 m/s) induce crystallization during fiber formation. The resulting preoriented yarns (POY) have to be stretched by only 40 – 100 % in subsequent steps (texturing). Additional polymer-specific increases in windup speeds lead to fully oriented yarns, which require almost no further stretching.

Wu et al. [77] succeeded to orientate spinning PET in a threadline modification process. The one-step orientation (without separate drawing) could be realized by the installation of a liquid bath in the spinline. High-performance filaments, however, have to be drawn after spinning to reach maximum fiber strength.

Liquid Crystals. Some linear polymers, in solution or molten form, tend to undergo self-organization by forming liquid – crystalline structures. Soluble linear polymers (lyotropic systems) form liquid crystals as a result of their rigid conformation and the formation of polyelectrolytes, e.g., the system poly(*p*-phenyleneterephthalamide) – H_2SO_4. Liquid crystals can also be formed in polymer melts (thermotropic systems). Examples of suitable systems are the aromatic polyesters of the poly(4-hydroxybenzoic acid) type or aromatic blocks built up in segments and separated by flexible spacers. Figure 2 E shows the resulting structures of some high-modulus aramids; pronounced amorphous intercrystalline areas are not visible.

5.5. Organization of Structural Elements

The arrangement of fibrils and fibril bundles in man-made fibers is controlled by the production procedure, i.e., by physical and physicochemical processes. Therefore, resulting structures depend on production parameters, and despite the different types of polymers employed, the tertiary structures of all man-made fibers are very similar.

In contrast, natural fibers have organized, evolved structures which differ considerably from each other, depending on the organism. Structural variations are reflected in different geometric positions of the fibrils with respect to the

Figure 2. Various conformations of fiber polymers

fiber axis (e.g., in cotton fibers) or in different chemical structures along the fiber cross section (e.g., in animal hair, such as wool). Fibers could thus be classified into two principal structural categories, namely, organized and unorganized, if the structure of each fiber were known.

5.6. Structural Models

The chemical structure of linear polymers determines the degree of conformational mobility of the chain segments of these molecules. Both chain mobility and molecular structure, in turn, greatly influence fiber structure. Flexible chain molecules may crystallize partially to form structures that conform with the classical crystalline – amorphous model (Fig. 3 A). Spandex fibers, on the other hand, have a special domain structure, because the chemical structure of these polymers changes considerably in the various segments along the polymer chain (Fig. 3 B).

The relatively planar structure of aramids and polyheterocyclic compounds, their conformational rigidity, and their tendency to form lyotropic structures in the spinning solution are consistent with a structural model in which the intercrystalline segments are bridged (Fig. 3 C).

Even more planar molecules form graphite-like structures (Fig. 3 D). Structural defects lead to cavities and weakly bent planes of the aromatic systems; for more details on carbon fibers, see → Fibers, 5. Synthetic Inorganic.

5.7. Molecular Symmetry and Physical Properties

The importance of molecular symmetry for thermophysical properties (melting point, glass transition temperature) can be demonstrated for polyamides. Figure 4 shows the fluctuation of melting points in the series of polyamides PA-3 to PA-13 (nylon 3 to nylon 13). Apparently, polyamides with an even number of carbon atoms and those with an odd number of carbon atoms belong to different structural series [47]. This can be explained by the different overall symmetry and, consequently, the different possibilities for hydrogen-bond formation (Fig. 5). In PA-7, more hydrogen bonds can be formed – at least in the all-trans conformation – than in PA-6. Analogously, all nylon types with an even number of carbon atoms have lower melting points than those with an odd number of carbon atoms (Fig. 5).

Figure 3. Various structural models of different polymer types
A: Classical structural model of amorphous – crystalline fiber polymers. Examples are polyamide, polyester, and viscose rayon. Long period (l) 10 – 30 nm.
B: Structural model of spandex fibers (polyurethane). Length of hard segment 2.5 nm; length of soft segment 15.0 nm
C: Structural model of aramid fibers (p-structures). No amorphous phases present; stretched molecules due to lyotropic structures during fiber formation
D: Structural model of carbon fibers; graphite structure with defects (cavities, bent layers; D = position of defect).

5.8. Changes in Properties Caused by Symmetry Defects

The incorporation of comonomers affects not only chemical structure, but also symmetry and, therefore, other fiber properties. For instance, the tacticity of polypropylene is changed by the insertion of comonomers, such as vinyl compounds. The resulting copolymer has altered properties and is no longer suitable for textile production. In addition, polar comonomers interfere with the isotactic course of the polymerization process itself.

Figure 4. Melting points of nylons as a function of chain length n.

Figure 5. Hydrogen bonding in nylon 6 (A; *mp* 225 °C) and nylon 7 (B; *mp* 232 °C)

Polyacrylonitrile is rarely used for textile fibers without comonomers being incorporated into the polymer, because the desired fiber properties (e.g., deformability, dyeability) cannot be achieved with polyacrylonitrile alone. This, of course, changes the solubility of the polymer.

Polyesters of similar chemical structure, but quite different molecular symmetry, also have very different melting points. For example, the

highly symmetrical poly(ethylene terephthalate) has a melting point of 265 °C, whereas the melting point of poly(*m*-phenyleneisopthalamide) is only 102 °C [47].

The same situation arises with aramids. Here, too, the highly symmetrical para-linked polyamides have higher melting points (in this case, decomposition temperatures) than the less symmetrical meta-linked polymers (Fig. 6). The different dipole orientation, oppositely directed or in the same direction (arrows in Fig. 6), and the total symmetry cause higher fiber tenacity and modulus.

Figure 6. Effect of dipole orientation on the melting point (decomposition temperature) of aramids

6. Fiber Properties Required by Textiles

Despite the fact that a large number of polymers possess the basic properties required for fiber formation, they are not all suitable for large-scale production of fibers. In textile production and in commercial applications, polymers must fulfill a variety of requirements:

1) *Chemical Stability.* Polymers must be stable under the influence of heat, light, air, water, and the chemicals commonly used in textile finishing and care.
2) *Thermomechanical Stability.* Polymers must possess the ability to be solution- or melt-spun and, at the same time, retain their dimensional stability during processing, use and care.

The requirements to be met by fibers and their parent polymers are, therefore, determined by the demands on the final products.

6.1. Requirements to Be Met by Textiles

The need for a variety of textile fabrics having specific properties should be clear from the diversity of textile uses. The priorities and order of importance of properties depend on the application in question.

For *clothing,* textile properties like appearance, aesthetics, optics, drape, formability (ironing, pleating), comfort, heat and moisture transport, handle, ease of care, and fastness of all types are of considerable importance. In addition, certain chemical requirements, such as dyeability, crease-resistant finishing, and dimensional stability, must be met in the production of textile materials. Finally, processibility to the finished textile product in partially automated production lines has become increasingly important.

Industrial textiles must also possess specific properties, depending on their application. For example, high tenacity is required for ropes; high modulus, for fiber reinforcement; heat stability, for protective clothing and insulation; high water absorption, for articles of hygiene; resistance to chemicals and flue gas, for filter materials; and long-term stability, for geotextiles [45].

In the past, fiber production and the utilization of specific properties were optimized primarily. Today, fibers with desired properties are made specifically to fulfill the requirements of the final product. The correlation between requirements and properties of the finished product and corresponding fiber (polymer) properties is given in Table 3.

6.2. Modification of Fiber Properties

The specific properties of the finished product depend directly on its end use. Since the fiber itself is not the final product, changes in fiber structure result in changes in the property profile

Table 3. Correlation of textile properties with fiber properties

Properties of the final product	Corresponding fiber properties
Optical properties	luster, fiber surface
Aesthetics	profile, fiber cross section
Mechanical properties	modulus of elasticity, tenacity, elongation
Comfort	
Physiological properties of clothing	moisture absorption, moisture transport
Antistatics	electrical resistance
Thermal insulation	heat capacity, porosity, heat conduction ∗
Hand	textile structure, bending modulus
Feel	roughness, modulus of elasticity, fineness
Ease of care and washability	wetting, moisture absorption, glass transition temperature (wet and dry) [78]
Dry cleaning	polymer (in)solubility, swelling
Soiling characteristics	zeta potential, adsorption and dissolution of soil components
Fastness	
Mechanical stability	tenacity, elongation, moduli, abrasion resistance
Dimensional stability	melting point, glass transition point (wet and dry)
Forming (e.g., pleating)	thermoplasticity, glass transition temperature (T_g)
Lightfastness	chemical structure, sensitizers, stabilizers
Lightfastness of dyeing	polymer – dye interaction, radical lifetime
Specific properties	
Flame resistance	chemical structure, combustion mechanism
Impermeability to water	moisture absorption, wetting properties
Water vapor permeability	surface properties, morphology, yarn structure
Dyeability	glass transition point during dyeing
Mechanical properties (ropes, material, tire cord)	modulus of elasticity, tenacity, elongation, dynamic modulus
Rubber elasticity	chemical structure, glass transition temperature, morphological structure, domain structure

∗ The thermal insulation of a textile is largely due to the air inside the pores, which is of low thermal conductivity.

of the finished product. Matching the requirement profile with the property profile is not always possible. the purpose of numerous modification procedures (e.g., of the fiber polymer, production method, processing, and finishing) is to confer special functional properties on the end product. some of these procedures are described in more detail in the following sections.

copolymers. Fibers are used predominantly as raw materials in textile manufacture. specific fabric properties, such as dimensional stability, brightness, color, pattern, or luster, are imparted to textiles during the physical and physicochemical processes of textile finishing. These characteristics should remain unchanged, particularly during use and cleaning. Chemical modification of the fiber polymer is generally employed to achieve this goal. Chemical treatment involves, above all, the introduction of special structural groups into the basic polymer, groups that are capable of taking part in polar and homopolar interactions with the chemicals used in textile finishing. Some examples are

1) introduction of a sulfonic acid group into poly(ethylene terephthalate) to bind cationic dyes (sulfoisophthalic acid as comonomer);
2) introduction of a sulfonic acid group into polyacrylonitrile with the help of vinylsulfonic or styrenesulfonic acid or a similar comonomer to make possible the use of cationic dyes;
3) introduction of flexible chain segments into poly(ethylene terephthalate) to change its dyeing characteristics. Polymer modification [copolycondensation with poly(ethylene glycol)] in the production of carrier-free dyeable polyester makes use of this principle.

Polymer Mixtures. Polymers are generally incompatible. If two different polymers are spun together, fibril structures are formed (matrix fibril fibers) that are known as *biconstituent fibers.* If two polymer streams are combined in the spinneret without blending, *bicomponent fibers* are obtained (→ Fibers, 3. General Production Technology).

Additives. Many specific fiber characteristics can be achieved by use of additives in the spinning solution or the melt. For example, the following effects can be obtained:

1) Delustering: use of titanium dioxide as additive in spinning
2) Spin dyeing: use of pigments as additives in spinning
3) Antistatic properties: use of electrically conducting additives in spinning
4) Flame resistance: use of flame retardants as additives in spinning

The use of additives in spinning produces a very broad spectrum of properties. For economic reasons, this type of fiber modification is the method of choice, if it produces the required effect. By comparison, the development of special polymers is a much more expensive procedure.

6.3. Comfort Properties of Textiles

Fibers used to produce clothing must possess a variety of properties. The term comfort refers to those properties responsible for the wash and wear performance of garments. Physiological studies have shown that apart from fiber substance, i.e., the chemical structure of the fiber polymer, the most important factors that influence textile wearability are fiber, yarn, and textile construction [50]. Along with moisture absorption, moisture transport across the fiber surface or through textile spaces is of particular significance for the moisture balance of textiles. Textiles must retain their appearance and form during washing and dry cleaning. In this connection, certain inherent fiber properties are of vital importance. The thermomechanical stability of textiles is controlled by the glass transition temperature (T_g) of the fiber polymers. However, this temperature is not a structural property but, rather, is directly related to the fiber system, e.g., the type of polymer and polymer – water interaction. Deformability generally increases with increasing moisture absorption because the chain-segment mobility of polymers is increased. The glass transition temperature of fiber polymers with a high moisture-absorbing capacity decreases dramatically with increasing moisture content. The resulting structural changes in the fiber lead to fiber shrinkage or stretching, depending on the degree of thermosetting. In other words, the textiles lose their shape.

Even in the dry state, dimensional stability decreases with increasing temperature, fibers can undergo permanent deformation at dry heat. Suitable fixation and textile finishing, e.g., thermofixation (heat setting) of polyester, felting or shrink-resistant finishing of wool, and crease-resistant finishing of cotton, can enhance dimensional stability and ease of care. Textiles that are still not dimensionally stable enough to be washed with water must be dry-cleaned. Here, soil release is achieved by using organic solvents such as perchloroethylene or fluorochloro-hydrocarbons (→ Dry Cleaning); the temperature must be maintained below the glass transition points of the fiber – solvent system throughout the process.

Figure 7. Total production of man-made fibers [2]

7. Economic Aspects

The production of natural and man-made fibers is influenced by a number of factors, such as demand (state of the economy), availability (production and trade), prices, and availability of raw materials. The per capita consumption varies

considerably from country to country and depends on climate, supply, domestic production versus imports, standard of living, fashion, state of the economy, and degree of industrialization.

The balance between the consumption of natural and of man-made fibers is also controlled by these factors, although a certain "awareness of nature" currently tips the scales in favor of natural fibers. The production of natural fibers, e.g., cotton or wool, is determined in terms of the profit made per area cultivated. A dramatic increase in production cannot be expected at present. However, new developments in genetic engineering could rapidly improve the yields obtained per given area.

The economic importance of individual fiber types can be deduced from their annual worldwide consumption [51], and Figure 7 shows the worldwide production of man-made fibers.

Both the consumption and the production of fibers also depend directly on the level of development and on per capita income [52]. The consumption per person in individual countries differs considerably for a variety of reasons. Some countries have already reached a high level of consumption, and despite their high standard of living, the population spends only a fixed percentage of their available income on textiles. The growth of fiber production for industrial use, on the other hand, is likely to continue. In 1984, 7 kg of fiber was consumed per capita; for the year 2000, a total fiber production of 43×10^6 t is expected if per capita consumption remains at 7 kg, or 48.6×10^6 t if it increases to 8 kg. The growth rate of 2.8 % achieved in the period 1968 – 1984 is not expected to continue. Up to 1995 the average growth rate was only 2.3 %/a. Nevertheless, a world fiber volume of about 50×10^6 t is expected in the year 2000 [52], [79].

The limited means of production in Eastern Europe also contributed to reduced consumption. In the developing countries, lack of spending power, capital, and means of production all combine to reduce growth of consumption. Regional differences in population growth will lead to an increase in fiber consumption in the developing countries.

8. Tabular Survey of Fibers [6], [53], [54]

A quantitative survey of the most important properties of fibers based on polycondensation and polymerization, as well as some inorganic fibers, is shown in Tables 4, 5, 6, 7, 8, 9, 10. Properties of these fibers, are compared with those of natural and semisynthetic fibers. The properties of all textile and industrial fibers are determined by variables related to production and aftertreatment. Hence, in general, only a range of values characteristic of individual fiber classes is given in this survey. In fact, only the order of magnitude is indicated for electric resistance of fibers because of considerable variations in measured values. No entries have been made when reliable information was unavailable.

The numbers in brackets are plausible estimated values. Figures for tenacity and modulus are based on both fiber fineness ($1\,\mathrm{tex} = 1\,\mathrm{g/km}$) and cross-sectional area of the sample. The following relationship is applicable:

$$\text{Fineness (tex)} = 10^5 \times \text{Density}\left(\mathrm{g\,cm^{-3}}\right) \times \text{Crosssection}\left(\mathrm{cm^2}\right)$$

In general, the characteristic stress – strain curve $\sigma(\varepsilon)$ of fibers does not show a constant gradient, even at low elongation. Hence, the modulus of elasticity is usually defined as the differential quotient $\mathrm{d}\sigma(\varepsilon)/\mathrm{d}\varepsilon$. Experimental determination at low fiber elongation ε is difficult but can be conducted successfully by extrapolation of the function $\mathrm{d}\sigma(e)/\mathrm{d}e$ for $e = 0$ [55].

The elastic recovery of a fiber (in percent) can be measured by standard methods [56] and is shown in Table 5 as

$$\left(1 - \frac{e_\mathrm{r}}{e}\right) 100$$

where ε_r = residual elongation, ε = total elongation.

Poly(vinyl chloride)	Clevyl, Rhovyl,...	disperse
Poly(phenylene sulfide)	Procon, Ryton	disperse

Figure 8. Specific tenacity (σ/ϱ) and modulus (E/ϱ) of high-performance fibers (ϱ = density)

Figure 9. Highest temperatures for fiber application without significant loss in tenacity

Values for fiber elongation, fiber shrinkage, and relative properties such as wet tenacity, loop tenacity and other parameters are expressed as percent. If properties such as fiber resistance to light, weather, chemicals, or organisms cannot be expressed numerically, they are characterized in a simplified qualitative manner in Table 9. In individual cases, the respective conditions and the type of attack (e.g., by certain kinds of pests [57], [58]) are such that widely differing results can be expected.

Some promising fibers that are still being developed have also been included, in particular, high-performance fibers made from high molecular mass poly(vinyl alcohol), the thermoresistant PEEK, PAI, PI (see Fig. 9, and the polyarylate " Ekonol," an example of a thermotropic polymer [59]. Among the inorganic fibers, apart from carbon and glass, the properties of silicon carbide, and ceramic fibers have been included. Figure 8 shows the ranges of Young's moduli and tenacities of presently known high-performance fibers used mainly for reinforcing organic resins.

Although fibers are highly anisotropic compared with other materials and therefore especially strong in the axial direction their Young's modulus is always inferior to the theoretical (crystal) modulus. The ratio of fiber to crystal modulus attains about 0.1 for textile commodity fibers, 0.3 for high-performance fibers (e.g., from HM-HDPE), especially those with extended chain structure, and as high as 0.8 for the LC polymer Kevlar 149 with unfolded, oriented PPTA molecules. The deficit of the fiber modulus is a consequence of incompletely uncoiled and disentangled macromolecules in as-spun and drawn fibers. The mechanical response of fibers is controlled by the fraction of taut tie molecules connecting neighboring crystallites. This fraction can be estimated from measurements of the elastic modulus by using a simple rheological model or other methods to be about 0.05 – 0.1 for drawn fibers [83].

Compressibility and lateral compliance increase with increasing fiber anisotropy (on drawing) and this is undesirable for reinforcing fibers (e.g., Kevlar or carbon fibers) in composites. In some cases thermal aftertreatment of such high-performance fibers allows a compromise to be found between the desired compressibility and lower tenacity (see also compressive strength of fibers in Table 4).

The applicability of industrial fibers at higher temperatures (see Tables 6 and 7) is of current

interest. Figure 9 reviews the thermal long-term stability in air.

This compilation of important data is by no means complete. For further information, see → Fibers, 4. Synthetic Organic and → Fibers, 5. Synthetic Inorganic.

1. Introduction

1.1. Fibers as Industrial Chemical Structures

In two important senses, fibers are structures. First, the definition of fibers as a particular form of matter depends on their gross structural size and shape. Second, they usually have a rich complexity of internal structure at several levels, which is determined by the biological or industrial circumstances of the formation of any particular fiber type and, in turn, determines the physical and chemical properties of the fiber as well as its utility.

The Textile Institute [1] defines fibers as units of matter characterized by flexibility, fineness, and high ratio of length to width. The geometrical aspects of this definition are paramount because even an inherently stiff and brittle ceramic material is flexible in the fiber structural form and, at the other extreme, a flexible rubber rod is

not a fiber. To provide a convenient quantitative marker in units commonly used in the man-made fiber industry, which can be converted to strict SI units, a typical fiber may be taken to have the following dimensional parameters:

Linear density 1 decitex (dtex)=10^{-7} kg/m
Length 1 cm
Density 1 g/cm^3

The International Organization for Standardization (ISO) has accepted tex, defined as grams per kilometer, as a unit of linear density within the SI system. However, an older unit denier, defined as grams per 9000 m, was widely used in the silk and man-made fiber industries. This has led to the adoption of decitex (dtex) as a common industrial unit.

Other derived parameters, if the fiber is assumed to be a solid with a circular cross section, are

Mass	1 µg
Diameter	11.2 µm
Length-to-diameter ratio	1120
Surface area	0.351 mm^2
Specific surface area	351 m^2/kg

The fineness of the structural division can be demonstrated by noting that a small piece (1 m^2) of a lightweight textile fabric (100 g/m^2) would contain a hundred million such fibers. The other structural aspect of the definition, the high ratio of length to diameter, intensifies the situation since fibers can interact, mechanically or otherwise, within a structure wherever they cross, as shown in Figure 1. Thus the essential fiber structural element should be taken as having a length equal to its diameter. The above parameters give the element a length of 10 µm and a mass of 1 ng, or 10^{12} fiber elements per kilogram.

Figure 1. Zone of interaction between two fibers over a distance approximately equal to the fiber diameter

The industrial situation is more complex than indicated by the "three ones" (1 dtex, 1 cm, 1 g/cm^3) of the example. The use of the word fiber in other contexts may cover other sizes. Even for fibers used in the textile industry, there are no precisely defined limits for the dimensions of what may be described without qualification as a fiber. For the natural fibers, which have been used for thousands of years, and the first generation of manufactured fibers, which together account for the major usage of textile fibers, the "three ones" are at the lower limit of fineness, length, and density. For these commercial fibers, the practical limits may be roughly given as follows.

Fineness ranges from about 1 dtex (10^{-7} kg/m) to 30 dtex (3×10^{-6} kg/m), giving diameters up to about 50 μm. Anything much coarser than the above limit of 30 dtex would be referred to as a thick *monofil* or *bristle*. From the last quarter of the 20th century onward, there has been considerable interest in finer fibers. Polyester *microfibers* are directly spun down to 0.1 dtex (10^{-8} kg/m) and finer still by using special techniques, such as the *islands-in-a-sea* procedure, in which fine component fibers are extruded within a removable, soluble matrix [2, 3]. *Nanofibers*, down to 10^{-7} dtex (10^{-14} kg/m) can be made by electrospinning, in which polymer melts or solutions are extruded in a strong electric field [4]. Carbon nanotubes are now being directly spun and collected as yarns [5, 6]. Other terms for finer fibers are *ultrafiber, superfine fiber*, *fibril*, and, for single crystals, *whisker*.

The shortest fibers used in the regular textile industry are about 1 cm in length, but shorter fibers are used in papermaking and in discontinuous-fiber composite reinforcement. The longest individual or *staple fibers* in commercial use are about 10 cm in length; however, man-made *continuous filaments*, occasionally produced as *monofilament yarns* but usually as *multifilament yarns* or *tows*, are effectively infinite in length (they can always be made longer by winding another turn on the package). The natural "continuous filament," namely silk, is about 800 m in usable length.

Density depends on the material, but the lightest common fiber material is polypropylene with a density of about 0.91 g/cm^3, depending on crystallinity. Most common textile fibers have densities between 1 and 1.5 g/cm^3, but the newer fibers such as carbon, glass, ceramic, and metal

fibers, used in composites and other engineering applications, have higher densities.

The structural form, emphasized in the above discussion, is the basis for the industrial exploitation of fibers. The consequences of the structure manifest themselves in several different ways. Traditionally, the fiber form provides the combination of flexibility and strength needed in textile materials for clothing and for a range of household and industrial uses. In modern high-performance composites, the crack-stopping characteristic provides the major advantage over bulk material. A second important feature in clothing is the large volume of space that can be trapped within a fiber assembly to provide softness and warmth; this is also significant in filtration and other industrial uses. Related to this feature is the high accessible surface area which is utilized in other applications. Continuity over long lengths is exploited by nature in nerve fibers and industrially in optical fibers. Networking deserves more exploration.

Finally, three fundamental, academic aspects are also of great industrial relevance:

1) Large structural defects, which are a major source of weakness in bulk materials, cannot occur in fibers. Any defect must be appreciably smaller than the fiber diameter.
2) Because fibers are so fine, their internal structure can be controlled in ways that cannot be used for bulk materials. Even a polymeric fiber, with relatively poor thermal conductivity, can be heated and cooled at rates faster than 1000 °C/s. Patterns of crystallization, which would be impossible with the slow cooling of large volumes, can thus give forms of fine structure that can only be found in fibers (or thin films). Metal fibers can be quenched at rates that result in crystalline (amorphous) glassy metals. Similar arguments apply to chemical changes, with fast diffusion through the fiber, and mechanical stresses. Thus, the chemical, thermal, and mechanical conditions that determine the form of fine structure can, in principle and to a considerable degree in practice, be controlled to a precise sequence, with minimum gradients disturbing the structure formation.
3) The third aspect relates to fibers in systems. In use, the fiber is a component in an assembly. Typically, a collection of fibers will make up a yarn, and yarns will be interlaced to make a fabric, which is the "material" used in the construction of the final product. Both within the fiber and in the arrangement of fibers in the assembly, the multiplicity of levels of structure, illustrated in Figure 2, can be exploited by the designer to achieve the required function. In simpler materials, many of these choices disappear, and some will be missing in various fiber systems.

Figure 2. Levels of structure within a fiber and in an assembly of fibers as a useful product

Questions of yarn, fabric, or industrial composite structure are beyond the scope of this article. The subject of fiber structure includes the external form but concentrates within fibers on large-scale inhomogeneities (zonal differences), fine structure (molecular packing), and chemical structure.

1.2. Structural Types

Within the increasing diversity of commercial fiber types, the most useful structural classification is based on the use of the fiber. The following categories are defined and treated separately in the following sections of this article: general-purpose textile fibers, high-stiffness fibers, and special-purpose fibers.

General-Purpose Textile Fibers For ordinary textile usage, a material is needed which can be produced in fiber form; has reasonable mechanical, thermal, and chemical stability, and can be colored by dyeing. However, the most restrictive feature in terms of structural possibilities is that the fiber must have intermediate elas-

tic extensibility, with a breaking extension between 5 and 50 % (usually between 10 and 30 %), as well as appreciable recovery from extensions near break. This rules out as too inextensible the common brittle materials such as crystals and glasses, and ductile materials such as metals; elastomeric rubbers are ruled out as too extensible. The only class of material structure that meets this requirement consists of partially oriented, partially crystalline, linear polymers.

High-Stiffness Fibers The new high-performance fibers used in advanced composites have more diversity of structure. The forms are

1) very highly oriented, highly crystalline linear polymers;
2) the graphitic, irregular, two-dimensional crystalline form of carbon fibers;
3) glass and ceramic structures; and
4) crystalline forms.

Special-Purpose Fibers Fibers for special purposes have an even greater diversity of structure, because a variety of materials can be made in fiber form when the incentive to exploit particular physical or chemical properties is present. Some of the more important materials are mentioned in the Section 5.4.

1.3. Development of Knowledge of Fiber Structure

Textile fibers were used for thousands of years before their structure was studied. During the first half of the 20th century, many studies by optical microscopy provided information on the gross structural features. Much information on a wide range of fibers is contained in [7] and [8].

Only in the 1920s was the polymer (macromolecular) hypothesis established; it was also recognized at that time that the natural plant fibers and regenerated rayons were composed of the linear macromolecule, cellulose and that natural animal fibers were composed of macromolecular proteins. This development coincided with the first X-ray diffraction studies of fibers, which demonstrated a combination of ordered and disordered material within the fiber. This was first interpreted as a dispersion of separate crystalline micelles within an amorphous matrix. However, in the early 1930s the molecular length was recognized as being much greater than the estimated size of the micelles; this led to the fringed micelle model in which the linear polymer molecules run continuously between crystalline micelles and the disordered regions. In the 1950s, the simple view was challenged in three ways: (1) by electron microscope studies which showed the presence of fibrils as a basic structural unit in many types of fiber; (2) by new ideas coming from fundamental studies of polymer crystallization, in particular, chainfolding in polymer single crystals and spherulitic growth in bulk crystallization; (3) by new thinking about the meaning of order and disorder. Some unifying ideas have been proposed, but possibly the most important point is that different fibers have different structures, so one can be specific only in relation to particular cases.

The early development of ideas of fine structure of fibers was reviewed in [9, Chapter 6], which also contains more detailed information on many fiber types; this reference was brought up to date in 1970 in [10]. The understanding and control of fiber structure is reviewed in [11], which covers both natural and manufactured fibers and introduces ideas from the science of complexity, including polymer dynamics, fractals, kinetics of nonhomogeneous processes, nonlinear systems, chaos, and the possibility that fiber formation involves quantum effects. Other books and reviews concerned with various aspects of fiber science and technology also include information on fiber structure [12 – 31].

2. General Features of Major Textile Fibers

2.1. Chemical Forms

This section is particularly concerned with the major textile fibers, which are discussed individually in Chapter 3, although the investigative techniques and some of the general comments are also applicable to the specialist fibers covered in later sections. Of the many linear polymers which have been synthesized in the laboratory or occur in nature, these major textile fibers of the 20th century consisted of only six basic chemical types. These fibers are listed in

Table 1, together with some less important ones. Others polymers have been tried for general textile use, and some may still be used in small quantities. In 2002, the Federal Trade Commission recognized a new generic fiber type: PLA, which is manufactured from poly(lactic acid) or poly(lactate) derived from naturally occurring sugars or starch. The commercial fiber has the trade name NatureWorks.

Table 1. Polymers in textile fibers

Class	Large-volume production	Small-scale or experimental production
1 Cellulosic	cellulose	
	secondary cellulose acetate	cellulose triacetate
2 Protein	keratin in wool	fibroin in silk
3 Polyamide	nylon 6 nylon 66	nylon 4, nylon 7, and others
4 Polyester	poly(ethylene terephthalate)	poly(butylene terephthalate) poly(trimethylene terephthalate), poly(ethylene naphthalate), and others
5 Vinyl/Acrylic	polyacrylonitrile	poly(vinyl alcohol), poly(vinyl chloride), modacrylic and others
6 Polyolefin	polypropylene	polyethylene

The desirable features of the polymer molecule are (1) it should be regular in order to form a crystal lattice, and (2) the stiffness of the chains and the interaction between them should be high enough to give stability to the crystal, but not so stiff as to cause difficulty in formation or excessive rigidity in the fiber. The principles of selection are illustrated in Table 2 by the various combinations of four simple groups in repeating polymer units. Chains composed only of methylene ($-CH_2-$) and ester ($-COO-$) groups are too inert and flexible to give a high enough melting point. However, inclusion of the amide ($-CONH-$) group, which interacts by hydrogen bonding, or of the rigid and electronically interactive benzene ring results in commercially successful polyamide and polyester materials. Nevertheless, these chains still contain sequences of $-CH_2-$ and $-COO-$, which provide enough flexibility. Experiments with other polyamides and polyesters suggest that six is about the right number of main-chain atoms to form such a sequence. If the flexible sequences are eliminated as in the aromatic polyesters and aramids, then the melting point becomes too high, with decomposition occurring first, and the materials are too stiff and intractable for general textile use. However, the ability of these polymers to form liquid crystals can be utilized to make high-modulus, high-tenacity (HM–HT) fibers.

The other synthetic route to obtain useful fibers by modifying the polyethylene molecule is to add side groups, which either are interactive, such as the polar $-C{\equiv}N$ groups in polyacrylonitrile and the hydrogen-bonding $-OH$ groups in poly(vinyl alcohol), or act like the $-CH_3$ groups in polypropylene and cause the chain to form a coil with greater flexural rigidity. In nature, more complicated forms occur, such as cellulose which contains a stiff ring and hydrogen-bonding $-OH$ groups, and proteins which have a variety of possible interactions.

Although the chemical structure of the synthetic polymer fibers thus seems simple, complexity can be introduced through copolymerization. End groups must, of course, be present, but other groups can be introduced to improve or modify dye affinity or to give other special effects. This is done in specialty polyamide and polyester fibers to give deep-dyeing effects or a selective attraction for particular classes of dyes. Copolymerization is always carried out on acrylic fibers, since pure polyacrylonitrile cannot be dyed; thus, considerable diversity exists in the chemical composition of acrylic fibers from different manufacturers, which have different trade names, or of different types having the same main trade name. The modacrylics are a more extreme example of copolymerization, containing less than 85 % acrylonitrile and adapted to give improved flame resistance or other special properties.

2.2. Polymer Characterization

In addition to their chemical composition, the physical form of polymer molecules must be characterized. With the exception of keratin, which is a complex protein system, the chains are normally linear with little branching or cross-linking, although cellulose fibers may be cross-linked by resin treatment of textile fabric to impart crease resistance.

Table 2. Various polymer forms

Type	Typical repeating unit	Comment
Aliphatic polyester	$-CO(CH_2)_2COO(CH_2)_2O-$	$mp < 100\,°C$, no use
Polyethylene	$-CH_2-$	$mp \approx 135\,°C$, little used as fiber
Polyamide	$-CO(CH_2)_4CONH(CH_2)_6NH-$	$mp \approx 260\,°C$, textile fiber
Polyester		$mp \approx 260\,°C$, textile fiber
Aromatic polyester		high *mp*, not used
Aramid		does not melt, high-modulus, high-tenacity fiber

The most important parameters are thus the degree of polymerization (chain length) and its distribution. Generally, the longer the chains, the greater is the fiber strength. However, the maximum degree of polymerization is limited by the conditions of formation. In the natural plant fibers, biosynthesis within the cell enables a very high degree of polymerization to be obtained. However, in the production of rayon fibers the mechanical and chemical attack necessary to get cellulose into solution, inevitably reduces the degree of polymerization. Considerable improvement in properties can be achieved by attention to detail, so that a high degree of polymerization is obtained. The elimination of low molecular mass fractions from the distribution is particularly advantageous. With synthetic polymers, the attainable degree of polymerization depends on the polymerization chemistry: addition polymers are generally able to reach high values, but condensation polymers are limited by the reaction equilibrium.

Although, for ultimate properties, a high degree of polymerization is desirable, this cannot be carried too far because the viscosity of the melt or solution will be too high for extrusion in spinning.

The average degree of polymerization may be found by standard techniques with measurement of viscosity or chemical end-group analysis being the most common. In particular cases, characterization of tacticity, or the form of copolymerization, whether random, block, or graft, may also be useful.

2.3. Other Chemical Constituents

Impurities. In addition to the polymer content, fibers usually contain within their structure appreciable amounts of other substances. In cotton, these include salts and other minor impurities, but in some plant fibers hemicelluloses and lignin may also be present in significant amounts. Wool contains various biological residues, and man-made fibers may contain catalytic residues, low molecular mass analogues such as dimers and trimers, and other manufacturing contaminants. All of these substances may be classed as impurities.

Pigments and Antistatic Agents. Some other constituents are deliberately introduced. Titanium dioxide particles are commonly added to man-made fibers as a delusterant, which gives a more matt appearance to fabric and increases opacity. Carbon black or colored pigments may be added to give a range of "spun-dyed" fibers. Such components are finely distributed within the fiber, but continuous strands of carbon or a colorless conducting polymer may be introduced to give antistatic fibers.

Water. Most of the polymers used in fibers absorb water, which is dispersed within the structure. At an intermediate humidity of 65 %, this gives a moisture content of about 13 % in wool and rayon, 7 % in cotton, 6 % in secondary acetate, 4 % in triacetate and nylon, 1.5 % in acrylic, and 0.5 % in polyester fibers; at saturation, without liquid water being present, some

fibers may absorb their own mass of water, giving a moisture regain of 100 % or a moisture content of 50 % based on total mass. The water will be absorbed predominantly in the noncrystalline regions of the fiber structure or on the surfaces of crystallites. The absorption may be divided between those water molecules that are located directly on active moisture-absorbing groups in the polymer (particularly −OH and −CONH− groups) and those that form secondary layers on top of the directly absorbed molecules. Because of its effects on dimensional swelling, heat of absorption, mechanical properties, diffusion within the fiber, thermal transitions, electrical conductivity, and other properties, moisture is an important element in the structure of many fibers.

Waxes, Lubricants, and Surface Finishes. Finally, other substances are commonly present on the surface of fibers. Natural fibers, as formed, contain oils and waxes, which are usually removed at some stage of chemical processing. However, in the production of man-made fibers and at various stages in the textile processing of all types of fiber, surface finishes are normally added to change the frictional properties of the fibers, usually to lubricate but sometimes to increase friction; frequently, to control static electricity; or for special purposes, e.g., to influence other properties such as wettability. The constitution of these surface components, which typically add 1 – 3 % to the total mass, is very complicated; they may contain a variety of natural oils, synthetic lubricants, industrial surface-active agents, and other substances. Little information has been published on this subject, but a review presents some information from patents [43].

2.4. Fine Structure

2.4.1. Characterization

The level immediately above the molecules is the most specialized and significant aspect of fiber structure in the context of industrial chemistry. Polymerization chemistry and the use of polymers in other applications are discussed elsewhere. The larger scale features are more a matter of engineering. However, the fine structure is characteristic of fibers, is rarely similar to structures found in other forms of the material, and results from the interaction of physical chemistry with the biological or industrial circumstances of fiber formation. This discussion is concerned with how the polymer molecules pack together and involves the range from 1 to 100 nm (10 to 1000 Å).

The linear polymer molecules in all general-purpose textile fibers are oriented preferentially parallel to the fiber axis to a degree which gives high anisotropy but is well short of perfect orientation. The molecules are ordered to about midway between the perfect order of a crystal lattice and the extreme disorder of an amorphous linear polymer, e.g., rubber or glass. The problem of characterizing fiber structure then has two aspects: (1) a qualitative description of the structural form which, while still being partially oriented and partially crystalline, can include many different models; and (2) establishment of the numerical values of relevant parameters, which may be general and relate to many structural models or may be specific to a particular structural concept.

Although various techniques provide information relevant to an understanding of fiber structure, they are all limited in what they provide and subject to artefacts, experimental error, and uncertainty of interpretation. Substantial, unambiguous information about fiber structure cannot be obtained from any single technique. One special danger is that if some particular form of model is assumed, experimental measurement may lead to a precise calculation of some parameter of that model. This will then reinforce faith in the model; yet if another model has been used as a starting-point, it too could be fitted to the experimental results with equal precision. The approach to understanding is thus a matter of integrating a diverse set of data from a variety of sources into a coherent unity. For some natural fibers, this has been achieved with confidence in the results; but for man-made fibers, a clear picture still does not exist.

The analytical techniques that provide almost all the information on fiber fine structure have been used for at least 40 years. Recent advances have occurred through some variation of methods, more powerful instrumentation, and — most important — the use of digital methods to collect data and computers to analyze data.

Degree of Crystallinity. If the fine structure is assumed to be a mixture of crystalline and amorphous material, the degree of crystallinity can be determined in various ways. If the density of the crystalline material is ϱ_c, of amorphous material ϱ_a, and of the fiber ϱ, then the degree of crystallinity δ_{cv} is the volume fraction of crystalline material given by

$$\delta_{cv} = (\varrho - \varrho_a) / (\varrho_c - \varrho_a) \quad (1)$$

The fiber density can be determined most easily in a density gradient tube containing a mixture of two liquids, graded so that the proportion of dense liquid increases from top to bottom of the tube, and calibrated by particles of known density. Experimental errors may be associated with such factors as absorbed water in the fibers, absorption of the test liquids, entrapment of air, and the presence of voids within the fiber. Usually, the dimensions of the crystal unit cell of the polymer are known accurately from X-ray diffraction studies, not necessarily on fibers, and the mass in the unit cell is known from the chemical composition, so that ϱ_c is known, although even here values are being challenged and revised. If the polymer can be quenched to an amorphous glassy state, then a direct measurement of ϱ_a can be made; otherwise, a value must be estimated by some form of extrapolation.

At best, there is some uncertainty about the true values of ϱ, ϱ_c, and ϱ_a; but the reality is worse. The best estimate of ϱ_c is for a unit cell within a large, perfect, unstrained crystal. Within the fiber, the crystals are very small, may contain imperfections, and are strained by the pull of connecting chains; each of these factors affects the density. Defining the true value of ϱ_a is even more difficult, because highly disordered structures may be packed with different degrees of efficiency. Aging of an amorphous structure enables the thermal vibrations to shake the structure down into tighter packing in a more favorable energy state. Furthermore, when a direct measure of amorphous density is available, (e.g., from a rapidly cooled polyester fiber), it is on a volume of material which is large in comparison to molecular dimensions and involves the dubious assumption that small regions of disordered chains, which connect crystallites by lengths of about ten repeating units, would have the same density as the bulk amorphous material. Also, because the scale of fine structure is so small, the interface regions between crystal and amorphous material constitute a substantial part of the whole, and the densities in these regions are likely to be different.

Finally, this whole discussion of degree of crystallinity is based on a tacit assumption that the fiber can be regarded as a two-phase mixture of a crystalline component and an amorphous component, typically represented by a model of crystalline micelles embedded in an amorphous matrix. However, the reality may be a more complicated distribution of intermediate degrees of order or, at the other extreme, a completely uniform, partially ordered, structure.

The problems arising from the application of Equation (1), which appears to be a very simple statement about fine structure, are discussed here at length because they also illustrate the nature of the uncertainties that arise in other techniques for investigating structure, which will be dealt with more briefly. The difficulties of interpretation in relation to models apply universally, but many of the more specialized techniques, while potentially yielding more detailed structural information, are subject to greater errors through artifacts of specimen preparation and problems of interpreting data.

An alternative definition of the degree of crystallinity exists, namely, the mass fraction of crystalline material:

$$\varrho_{cm} = (V_a - V) / (V_a - V_c) \quad (2)$$

where V, V_a, and V_c are the specific volumes, which are reciprocals of the respective density. Since the difference in densities is not large, the two quantities will not differ greatly.

Although one must be very cautious about a precise and absolute interpretation of the degree of crystallinity, the fractions defined in Equations (1) and (2) provide a scale of degree of order in fibers, from poorly ordered to highly ordered, even if the scale is arbitrary and empirical. This interpretation would only be upset in highly exceptional circumstances (e.g., in ice and water) where the ordered crystal lattice had a lower density than the disordered arrangement.

Other physical and chemical measurements can be used to define the degree of order (degree of crystallinity) by equations analogous to (1) and (2). These include *refractive index*, which is proportional to density; *moisture take-up*, which occurs within amorphous regions but usually not

within crystalline regions, although absorption will occur on crystal surfaces; other *absorption techniques*; and *latent heat of melting*, although here the fraction would equal the ratio of fiber latent heat to crystal latent heat (L/L_c), because of the assumption that the amorphous material does not contribute. Other techniques exist in which the responses X_c and X_a from the crystalline and amorphous materials can be separated, so that the relevant fraction becomes $X_c/(X_c + X_a)$. Such techniques include X-ray diffraction, electron diffraction, infrared absorption, NMR and Raman spectrometry. However, the problem here is that the two responses overlap, so the separation of X_c and X_a is uncertain.

Provided any errors of experimentation or interpretation directly associated with the techniques have been eliminated, all the above methods give the same value of the degree of crystallinity for a simple model of large crystals dispersed in amorphous material (like a mixture of crystals and liquid in an organic compound at the melting point). However, when the real structure is not defined so simply, the results will differ because each technique will be defining a different scale of the degree of order.

X-Ray Diffraction. One of the most useful techniques for studying fiber structure is wide-angle X-ray diffraction, in which a beam of X-rays is passed through a bundle of parallel fibers. Specialists should be consulted about the minimization of errors associated with the X-ray source and its collimation, specimen preparation, the method and geometry of detection (photographic film or solid-state detection), and the extraction and interpretation of quantitative data. Because of the inverse form of Bragg's law, $\sin\theta = n\lambda/2d$ (where θ is the angle of a strong reflection from a crystal lattice, n is an integer defining the order of the diffraction, λ is the X-ray wavelength, and d is the crystal lattice spacing), wide-angle scattering (WAXS) gives information at the level of atomic spacing, whereas small-angle scattering (SAXS), which requires a different instrument, gives information on larger scale structural features.

A perfectly crystalline, perfectly oriented fiber would give a wide-angle X-ray diffraction pattern of the form shown in Figure 3A (a). The symmetry of crystals oriented parallel to a single axial direction, but with random orientation around this axis, leads to the reflections from particular lattice spacings appearing on layer lines, with the separate orders at increasing distance from the meridian. Real textile fibers give patterns of the form indicated in Figure 3B (a). The first-order reflections are easily seen, but higher orders are usually very faint. The sharp spots are diffused, and more general scattering occurs in the form of a halo from disordered material.

The relation between various features of the X-ray diffraction pattern and structure is as follows:

1) Location of spots: size and shape of unit cell; arrangement of atoms in crystal lattice
2) Radial broadening of spots: increasing with reduced size and perfection of crystals
3) Circumferential spread into arcs: decreasing orientation of crystals
4) Ratio of sharp spots to diffuse scattering: degree of crystallinity

Figure 3. A: Perfectly crystalline fiber; B: Typical fiber a) Simplified representations of wide-angle X-ray diffraction patterns; b) Radial scans of intensity I against an interval of radius r, showing peaks broadened to a half-width w, superimposed on an amorphous background A; c) Scans along a circumferential arc of intensity I against polar angle ϕ, showing broadening 2 θ resulting from range of orientation

In Figure 3 (b) and (c) is illustrated how quantitative parameters can be determined roughly,

but much more detailed analysis is needed to get precise measures. In principle, the complete X-ray scattering contains information from the complete pattern of packing within the fibers, including the size, shape, and perfection of the crystals and statistical features of the amorphous material. The problem is to devise analytical schemes to extract this information without misinterpretation.

The small-angle X-ray scattering pattern consists of diffuse spots from which an indication of long spacings within the fine structure can be obtained.

The techniques continue to advance. Digital collection of data and computational analysis increase the useful information which can be generated. The use of intense synchrotron sources of X-rays enables information to be obtained in much shorter times and allows dynamic studies of structure development in a threadline to be performed.

Electron Microscopy. Transmission electron microscopy is another source of information, which has proved particularly useful where there are well-defined structural units. Thus the cellulose in cell walls can be shown to be in the form of fine fibrils, either by disintegration or by taking surface replicas (→ Cellulose); and in wool, transverse and longitudinal sections can be cut and stained, and clearly show a fibril – matrix composite structure, with dimensions that can be measured (→ Wool). However, these simple statements hide the great skill and care needed to extract useful and reliable information. In man-made fibers, where the structure is less well-defined, information is more difficult to extract, but new techniques of high-resolution electron microscopy on thin sections show promise. A particularly promising technique is the use of high-voltage electron microscopy on thick sections. By tipping the specimen, information of the three-dimensional structure can be obtained and shown by tomography. This method has been used by Bryson et al. [44] to determine the helical angles in macrofibrils in wool.

Electron Diffraction. Electron diffraction generates the same sort of information as X-ray diffraction, but because it is carried out with a minute beam on a thin specimen, it can be used to distinguish different areas of a cross section and different directions in the fiber.

Other Microscopy Techniques. Since its introduction in the 1960s, scanning electron microscopy (SEM) has been used to study the overall form of fibers, and, particularly, the details of fiber fractures [45]. Recent advances in high-resolution imaging enable finer structural details down to 1 nm or less to be examined [46].

Atomic force microscopy is being used to investigate coarser features of fiber structure, such as the cell structure in wool, and to measure the mechanical properties of individual structural components. Refinements of the technique are likely to improve resolution.

Due to limits on resolution and contrast, it is not possible to obtain much information about the internal structure of fibers by conventional optical microscopy. However, the development of confocal light microscopy now allows coarser features, such as the cells in wool, to be observed. In this technique a small spot of light is scanned across the specimen at different depths. The resultant reflected or fluorescent light is picked up on a detector and gives images of successive cross sections of a fiber.

Infrared Spectrometry. Infrared spectrometry can be used to detect the presence of particular chemical groups, but its relevance to fine structure results from the fact that the absorption frequency changes with the environment of the group. Degree of order can be determined by separating the bonds associated with crystalline and amorphous materials. A difference also exists between *cis* and *trans* configurations, and crystallographic chain folds may give a characteristic shift. Other information can be inferred from the change of frequency with the state of strain of a fiber. The use of polarized infrared radiation can yield data on orientation of absorbing groups in the material. Infrared absorption, particularly with high-speed Fourier transform techniques, has been very useful in polymer studies, but problems of suitable arrangement have limited its value in studies of fibers.

Raman spectrometry. In its simplest form, Raman spectroscopy gives information similar to infra-red spectroscopy. However its value has been transformed by the introduction of the Renishaw Raman microscope. Now, in addition to

detecting local differences in molecular environments, the shift in bonds can be calibrated to determine molecular strains.

Nuclear Magnetic Resonance Spectrometry. Another major analytical technique used to a small extent to obtain information on fibers is nuclear magnetic resonance. STATTON [47] pioneered the use of wide-line NMR, which relates to mobility of molecular segments within a fiber structure, but the method has not been used much since his work.

Refractometry. Use of the refractive index as a measure of density has been mentioned, but the most important use of an optical technique is the determination of birefringence as a measure of orientation. This is one of the most straightforward methods since, apart from any errors resulting from form birefringence, the difference between the refractive index n_1 for light polarized parallel to the fiber axis and n_2 for light polarized perpendicular to the axis is directly related to the orientation of groups contributing to the dipole moment. The Herman's orientation function f, defined below in terms of n_1 and n_2, is related to the average angle of inclination of molecular segments, ϕ:

$$f = (n_1 - n_2)/(n_1' - n_2') = 1 - 3\sin^2\phi/2 \quad (3)$$

where n_1' and n_2' refer to a perfectly oriented fiber.

The orientation determined in this way relates to the whole fiber, whereas the crystal orientation is given by X-ray diffraction. The average amorphous orientation can be calculated from the other two values.

Dichroism. Dichroism, including fluorescence methods, is another optical technique for determining orientation. Other structural information can be inferred from light scattering.

Thermal Analysis. The use of latent heat as a measure of crystallinity has been mentioned, but the complete differential scanning calorimetry (DSC) or differential thermal analysis (DTA) response contains more information. The presence of multiple endotherms indicates the existence of different structures, with the more stable forms, such as larger crystals, melting at the higher temperatures. Generally, any endotherm or exotherm is an indication of some structural change.

Other Sources of Information. In addition to the analytical techniques, two other important sources can be used to understand fiber fine structure. The first is a consideration of the way in which the molecules would be expected to behave under the conditions of fiber formation. This involves an application of knowledge of the movement and deformation of polymer molecules and of polymer crystallization, and varies with the chemical constitution of the polymer.

The second is the relation between structure and various physical and chemical properties. For example, a difference in appearance after dyeing is perhaps the most sensitive way of detecting a structural change, but this cannot be interpreted easily. The range of properties related to structure includes diffusion and accessibility; mechanical and thermomechanical responses, particularly dynamic modulus studies; electrical properties; and others. Attempts to explain these properties lead circumstantially to views about fine structure. Most certainly, if a particular structural model gives good predictions of properties without the use of adjustable parameters, this is strong evidence in support of the model.

2.4.2. Models

The first widely used model of textile fiber fine structure was the *fringed micelle* model, illustrated in Figure 4. This model reconciled the indications of the presence of both crystalline and amorphous regions with the great length of the chain molecules by postulating that a given molecule fringed in and out of the crystalline micelles. In fibers, as distinct from unoriented polymer forms, the orientation was assumed to be preferentially parallel to the fiber axis. This model was plausible because it might be expected to occur if crystallization started at many places within the fiber. Furthermore, it gave reasonable explanations of many fiber properties.

When chain folding in polymer crystals was discovered, a *modified fringed micelle* structure was suggested (Fig. 5). This model shows a mixture of chain folding and fringing at the edge of each micelle, and recognizes that relatively high degrees of crystallinity, such as 50 %, can only be accommodated if the micelles are regularly

stacked in a pseudofibrillar array. If required by the crystal lattice, the ends of the micelle will be angled. Models of this sort, proposed by various scientists, remain the best working models for some types of fiber.

Figure 4. Fringed micelle model, as drawn by Hearle [48]

Figure 5. Modified fringed micelle model, as drawn by HEARLE [49]

Characterizations such as Figures 4 and 5 are not explicit theories of structure. They are inadequate pictorial representations of poorly defined views of structure. They do not attempt to be quantitative in terms of size, shape, and spacing of crystalline regions or of molecular paths in amorphous regions. Differences in representation by different authors reflect artistic skill and temperament more than scientific intention, as well as the limitations imposed by size and a two-dimensional format.

An attempt by MURTHY et al [50] to give a more quantitative picture of the structure of a nylon 6 fiber on the basis of SAXS and WAXD data is shown in Figure 6. The main features of Figure 5 can be seen, but with more irregularity in the structure.

Figure 6. The structure of a nylon 6 fiber, as envisaged by MURTHY et al [50] on the basis of SAXS and WAXD data. 1) Fibrils; 2) Lamellae; 3) Partially extended chains in the interfibrillar regions; 4) Tie molecules in the interlamellar regions; 5) Free chain ends; 6) Amorphous segments with large free volume, which may give rise to voids; 7) Fusion of adjacent microfibrils. Shaded areas represent the interfibrillar amorphous regions.

In some fibers, evidence suggested that the crystals might be in the form of long fibrils, and this led to the suggestion of a *fringed fibril struc-*

ture (Fig. 7). *Fringed lamellar forms*, (Fig. 8) are also possible, but they are more likely to occur in bulk polymers than in fibers.

Figure 7. Fringed fibril structure, as drawn by HEARLE [51]

All these models are two-phase structures in which crystalline and amorphous regions are clearly differentiated. A radically different approach is to propose a *uniform one-phase structure* of intermediate form. HOSEMANN [53] investigated the paracrystalline structure in which the disorder results from a statistical deviation from the true lattice spacings: this maintains an approximation to short-range order, but means that there is no long-range order. KARGIN [54], from the other direction, suggested that no real crystallinity exists, at least in some types of fiber, and that the structure is amorphous, with a degree of order introduced by some correlation between the positions of neighboring molecular segments.

Figure 9. Dynamic crystalline gel model in oriented fiber, as drawn by HEARLE [10]

Adopting a somewhat more localized view, RENEKER [55] has explored the explanation of disorder as the result of particular forms of crystal defect, somewhat analogous to dislocations in metals; this is probably a useful representation for polyethylene and other chains with short repeating units. On the other hand,

Figure 8. Fringed lamellar structure, as drawn by HEARLE [52]

Figure 10. A: Schematic representation of examples of degree of order from amorphous (zero) to the perfect crystal (one); B: Distributions with different degrees of localization of order
a) Uniform at degree of order of 0.5 (zero localization); b) Perfect crystal plus amorphous (maximum localization); c) Hypothetical distribution with all degrees equally represented; d) Mixture of high and low order (moderate localization)

Hearle [56], following a thermodynamic consideration of multiple melting in nylon and polyester fibers, has suggested a *dynamic crystalline gel* in which small molecular segments are in register throughout the material, as illustrated in Figure 9.

According to another view, amorphous material as such might not be present, but the structure may be an assembly of fine crystalline fibrils with disorder coming from imperfections in the packing of the fibrils. The density, for instance, would be reduced by the space between fibrils.

Considerable conflict and diversity of view about fiber fine structure appear to exist, but two important points must be remembered: (1) different fibers have different structures, so different choices of model will give the best representation for particular fibers; (2) real structures are likely to be much more complicated than the models, which are usually simplified to an extreme in an attempt to clarify understanding. Real fibers are likely to show features from several models. All the structures can be represented as a distribution of paracrystals in a matrix of partially correlated disorder, with the possibility of localized defects in the crystal or localized segments in register in the amorphous part, although such a description is too general to add much understanding.

2.4.3. Unified Parametric Approach

An alternative way of dealing with the problem is to try to define a set of parameters that are generally applicable and describe important aspects of structure.

A perfectly crystalline material can be described by a limited number of coordinates in a crystal lattice, and a highly amorphous material by a limited number of statistical parameters. Structures of intermediate order can only be truly described by specifying the location of every molecular segment in a region large enough to be typical of the whole. This would lead to a set of parameters approaching Avogadro's number, so that one would have to be highly selective in choosing a reduced set!

The most useful parameters appear to be the following:

1) Degree of order
2) Degree of localization of order
3) Aspect (length-to-width) ratio of crystalline units
4) Degree of orientation
5) Size of crystalline units
6) Molecular extent

The idea of order is discussed above in relation to measurement of "crystallinity." Theoretically, a *degree of order* could be defined as a parameter based on statistical correlation between vectors representing neighboring molecular segments. In a perfect crystal, the vectors would be perfectly correlated in location and direction; at maximum disorder, there would be no correlation. Practically, a scale of degree of order can be defined by density or some other measurable quantity. In a uniform structure, the degree of order can vary continuously between the two extremes as illustrated in Figure 10A.

The idea of *localization of order* is then illustrated by Figure 10B. An average degree of order at some intermediate value, say 0.5, can be given by many different distributions. At one extreme (a), the whole material can be uniform, with zero localization of order. At the other extreme (b), the structure may be completely localized with perfect crystals embedded in a wholly amorphous matrix. Another form (c), at an intermediate degree of localization, would have equal regions of all degrees of order. These simple idealized forms are unlikely to occur in real fibers; the most common form is likely to be some variant of (d), namely, imperfect crystals mixed with varied disordered material, but certain fibers do tend more to the extremes of very high localization or complete uniformity.

The *aspect ratio*, or ratio of length to width, is a measure of the shape of the crystalline regions (with the assumption that the localized units are the highly ordered parts dispersed within a disordered matrix). This can range from infinity to one, through fibrils of great length, limited length, and elongated micelles, and then from one to zero through short, wide micelles, lamellae of limited width, and very wide lamellae, as illustrated in Figure 11.

Figure 11. Shapes of crystalline regions of varying aspect ratio, decreasing from top to bottom

The different models of structure described in Section 2.4.2 can then be located on a three-dimensional plot, as shown in Figure 12. However, different models, with subtle differences in molecular packing, can occupy the same place in the diagram, and a continuous range of structures exist, which merge imperceptibly from one form to another. The named models are idealizations which lead to simple description. Figure 13 indicates where different types of fibers lie on such a plot. The justification for the location, and the uncertainty, will become apparent in later sections dealing with particular fibers.

Fortunately, the three parameters plotted are enough to describe the essential character of a structure. The other features can be regarded as superimposed on the basic form.

Figure 12. Representation of models of structure on a three-dimensional plot with axes (1) degree of order, (2) degree of localization of order, (3) aspect ratio of localized units
Forms are: a) Wholly amorphous; b) Amorphous with correlation; c) Paracrystalline; d) Perfect crystal; e) Amorphous with varying correlation; f) Crystalline with distributed defects; g) Networks of regions of high and low order; h) Crystalline with concentrations of defects; i) Fringed fibril; j) Fringed micelle; k) Fringed lamellar

Figure 13. Estimated location of fiber types on the plot of Figure 12
a) Rubber, glassy polymer; b) Acrylic; c) Melt-spun polyethylene; d) High wet modulus rayon; e) Rayon; f) Nylon, polyester; g) Aramid, high molecular mass polyethylene; h) Polyurethane (spandex); i) Wool; j) Cotton

Any of the suggested fiber structures can occur at varying *degrees of orientation*. As discussed with relation to birefringence in Section 2.4.1, the degree of orientation is a quantity which is easily defined as some average of the orientation of individual molecular segments, and easily measured. Crystallite orientation is simply related to the distribution of crystal axis angles, such as those shown in Figure 4, relative to the fiber axis. In natural fibers, as discussed below, genetically controlled mechanisms lead to helical forms of orientation. For melt-spun fibers, such as nylon and polyester, it is not accidental that Figures 5 and 6 show perfect crystallite orientation. Orientation is induced by drawing with a typical draw ratio of 4:1. The combination of high draw and a crystallinity of around 50%, which implies that in each 3D direction the spacing between the micellar crystals is, on average, one sixth of the crystallite dimensions, means that a very high degree of crystallite orientation is inevitable. Amorphous orientation is given by the distribution of angles of molecular segments. Earlier drawings, such as Figures 4 and 5, tend to show an almost random distribution of angles, but the more specific model of Figure 6 shows a fairly high degree of amorphous orientation. In wholly amorphous polymers, such as rubbers, orientation of molecular segments occurs during stretching and can be set by cooling below the glass transition temperature, only to be released on heating. In the melt-spun fibers the orientation is induced by the draw tension and the driving force that pulls molecular segments into crystallites. On release of the draw tension, the geometrical constraints of the structure limit the extent to which de-orientation of molecular segments in the amorphous regions is possible.

The *size of the crystalline regions* in any of the structures can range from small to large. The structure may have a fine texture, with small crystallites close together, or a coarse texture with large crystallites farther apart.

The first five parameters are all obvious characteristics of fine structure. The concepts are clear, and qualitative comments and rankings can certainly be made, although experimental difficulties in measurement can arise and debate may occur about the best mathematical forms of definition and about problems in interpreting measurements. Any diagram of fine structure includes implicitly the information needed to calculate values of each parameter, even if the diagrams are so simplified that the values are not realistic.

The sixth parameter, *molecular extent*, is a less obvious structural feature. It has never been measured directly and could not be estimated from a typical diagram because the relevant information is contained in molecular paths over distances greater than those shown in the diagrams. However, molecular extent almost certainly ranks equally with the other five parameters in determining important fiber properties.

Figure 14. A: Definition of molecular extent, either as an extreme value E_m or an average value, E_a
B: Molecular extent with crystallographic folding
C: Molecular extent without crystallographic folding

Figure 14 A illustrates the basic definition, with Figures 14 B and C giving examples in micellar structures with and without crystallographic folding. Molecular extent is a measure of the distance over which the molecule extends. Particular definitions might relate either to the extreme value E_m or to some average of length of the folds E_a. In principle, molecular extent could be measured in different directions, but in fibers the molecular extent parallel to the fiber axis is important. As obvious from Figures 14 B and C molecular extent is closely related to two frequently discussed structural features: the number of chain folds and the number of tie molecules between crystals. In an amorphous isotropic polymer, it would be related to radius of gyration.

Reference to the analogous quantity in textile yarns spun from short fibers like cotton or wool might be helpful. As the material comes from carding, the fibers are folded backward and forward, and thus have a limited fiber extent. Various drafting operations then pull the fibers out into more extended forms until, in the limit, the fiber may be fully extended along the yarn with no loops or folds. This increases yarn strength because any fold is as much a source of weakness as a fiber end, since both interrupt continuity in the transmission of stress. The fiber extent can be measured experimentally by incorporating colored tracer fibers, but an analogous procedure is not possible for the molecules within the fiber. Neutron scattering of deuterated molecules might be a way of estimating molecular extent, but the experiments would be very expensive.

The three different parameters — degree of order, degree of orientation, and molecular extent — must not be confused. The problem is that at the extremes, which never occur in practice, they do become identical, as shown in Figure 15 A and B. A tendency exists to assume that they go together through the intermediate states. However, this is not so, and Figures 15 C – F give various schematic examples of structures in which one parameter is high and another low. Analogous situations will occur in the real structure of textile fibers.

As stated at the start of this section, specification of six parameters still leaves open an infinite range of possible structures, with a large number of forms showing significant differences. Other features which can be discussed in the context of the structure of particular fibers or which must be considered in theoretical analysis of the relation between structure and properties include (1) more detailed specification of the size and shape of crystalline regions; (2) the nature of imperfections within crystals; (3) the form of molecular

Figure 15. Schematic illustration of independence of degree of order, degree of orientation, and molecular extent, except at the extreme values

packing in amorphous regions; (4) the relative positions of crystallites on a regular or irregular superlattice; and (5) details of the interconnections between crystallites.

2.4.4. Relation to Fiber Properties

Although the relation between fine structure and fiber properties can be discussed in detail only in the context of particular fiber types, some general trends can be mentioned.

Crystallinity tightens the structure and gives it greater stability. Consequently, increasing degree of order usually yields increased strength (unless bad stress concentrations are present) and increased stiffness, reduced moisture absorption and accessibility to chemicals such as dyes, and increased dimensional stability under changes of temperature and humidity.

The *degree of localization of order* seems to have little influence on most mechanical and other physical properties. A low degree of localization gives a uniform structure: if this reflects the coherence of ordered material, diffusion within the fiber will be resisted; but if, as is more likely particularly in hot or wet conditions, this represents the mobility of disordered material, then the movement of substances such as dyes will be relatively easy. Generally, low degrees of localization of order will be thermodynamically unstable, so that such materials can be set in a more stable form with an increase in the localization.

Crystallite aspect ratio has a major effect on mechanical properties, with a high ratio promoting greater stiffness (initial modulus), which is usually associated with reduced extensibility and greater strength.

Degree of orientation has a major influence on mechanical properties, as illustrated by the family of stress – strain curves in Figure 16. As indicated below, this is also a parameter that can be controlled easily. Increasing orientation trades extensibility for strength, with the breaking points lying on a locus of increased tenacity T and reduced breaking extension E, which approximates to a constant value of $T\,E^{1/2}$. The initial modulus also increases. For clothing and household uses, the softer, lower modulus fibers are preferred, and the lower strength is adequate. For industrial uses such as tire cords and ropes, the more oriented high-tenacity fibers are preferred [57].

Figure 16. Family of stress – strain curves, showing effect of increasing orientation (→ O) or improving structure (→ S)

The *size of localized units* does not have much influence on the initial part of the stress – strain curve, but it does influence the strength. A reduction in value is one way of improving structure, which moves the locus of failure in Figure 16 further out. This is because a coarse structure of larger units tends to give greater stress concentrations and less effective connections between crystallites, with more free ends and fewer tie molecules. An increase in size also makes the spaces between crystallites greater, and this increases the mobility of dye molecules. Treatments that change structure in this way are thus prone to cause unsightly dye streaks in fabrics if they are not well controlled.

Increasing *molecular extent* is another way of increasing the strength of a structure, usually associated with some increase in stiffness. This will also push the locus of failure in Figure 16 further out, since a high extent means that the structure is more strongly connected along its length. The mechanics can be analyzed in terms of slippage, which occurs at free ends of molecules or at folds, and leads to a lack of contribution to tension.

2.4.5. Relation to Fiber Formation

The development of fine structure can also be discussed in detail in relation to particular materials and manufacturing methods, but once again, a few general comments can be made. An important distinction exists between natural fibers and man-made fibers. The former, except for silk, are laid down very slowly as living cells over a period of days, weeks, or months, under the genetic control of mechanisms of biosynthesis of the polymer in living organisms. This leads to highly specialized structures. In contrast, man-made fibers are formed from a melt or solution of the polymer by high-speed manufacturing operations. Typical spinning speeds will range from 500 to 5000 m/min (ca. 10 to 100 m/s), so that the solidification which establishes the structure, occurs in a fraction of a second. The manufacturer is thus left with what happens in the transition from disorder to partial order, and this is likely to be a rather poorly defined structure. Thermodynamically, the structure will be metastable, so that in the melt-spun thermoplastic polymer fibers, it can be changed by subsequent heat treatment at temperatures approaching the melting point. The structure of fibers, like cellulose or the acrylics which can only be spun from solution because they decompose before they melt, will be less easily changed, since this would require the action of plasticizing or swelling agents, such as caustic soda which changes the structure of cotton in mercerization.

A particular example of the difference between natural and man-made fibers is shown by the *degree of order* in cellulose fibers. Natural plant fibers, like cotton, have a crystallinity of about 66 %, but rayon only reaches about 33 %. Rapid crystallization from a disordered solution or melt leads to crystallinities which are characteristic of the polymer stiffness and complexity. Therefore, nylon and polyester will give values of about 50 %, but linear polyethylene can give higher values. Usually, different treatments will not change the value by more than about

± 5 %. However, when a different manufacturing method is available, such as the liquid crystal systems used in aramids or gel spinning for high-modulus polyethylene, much higher values can be attained.

The *degree of localization of order* is also an almost inevitable consequence of the manufacturing system, although it may be increased by heat treatment of thermoplastic fibers.

The *aspect ratio* of the crystallites depends on the circumstances of crystallization, which are not usually amenable to control in manufacturing, with rapid crystallization from a disordered state tending to give micellar crystals. The contrast between natural and regenerated cellulose fibers is again instructive: the former are fibrillar, but the latter are usually micellar. By changing the chemistry of the regeneration of viscose rayon, crystallization can be delayed until the fiber is solid and oriented, and this does lead to a more fibrillar form of rayon with a higher modulus.

Degree of orientation is easy to control in manufacturing operations, so that the family of products represented by Figure 16 can be generated. Orientation may be increased by increasing the stretch imposed either between extrusion and solidification, provided the spinning speed is high enough to limit relaxation, or in a subsequent drawing operation. In thermoplastic fibers, orientation can be increased further by hot stretching of yarns or reduced by relaxation and shrinkage. Thus, the fiber manufacturer has a number of ways at his disposal to adjust orientation. Technically, no lower limit exists, but the market only requires products with orientations above a certain level. An upper limit to what can be achieved without breaking fibers does exist, however, usually at around 10 % breaking extension. Other mechanisms are involved in producing the high orientation of the high-modulus, high-tenacity fibers.

Crystallite size is not controlled easily, except that it tends to be increased by heat treatment of thermoplastic fibers. Major changes in manufacturing methods also cause differences. Thus a change in the chemistry of regeneration of viscose rayon fibers, with the sodium cellulose xanthate going through an intermediate zinc cellulose xanthate before being converted to cellulose, leads to a finer structure than is achieved by direct generation. High-speed spinning of polyester fibers, in which all the orientation is induced in the initial spinning operation, seems to give a structure with larger crystallites than a process of solidification followed by drawing.

Molecular extent is also not easy to control, except by the use of special techniques such as gelspinning, or by biological control, which gives a very high value in natural cellulose fibers. In manufacturing from solution or melt, the molecular extent will depend on the natural configuration of the molecule in the disordered state, represented by a radius of gyration, transformed by the elongation during fiber formation.

2.4.6. Structural Transitions

Fiber structure is often pictured in static terms, like an instantaneous snapshot of some geometric pattern. However, the dynamics, particularly the transitions between different degrees of mobility, also have to be considered.

The major transitions such as melting and chemical decomposition lead to a loss of fiber identity. In principle, any linear polymer is thermoplastic and will melt, but in practice, a distinction exists between those that melt and those that decompose and char before a melting temperature is reached. The chief thermoplastic fibers are nylon, polyester, polypropylene, and triacetate. Close to the melting point, the structure develops a degree of mobility, particularly if it has not been annealed for a long time to develop large stable structures. Consequently, these fibers can have their structure permanently changed, or heat-set, by high-temperature processing. The chief decomposing or charring fibers are cellulose and polyacrylonitrile. Wool and secondary acetate tend to liquefy and decompose simultaneously.

Below the melting point, glass transitions occur which have some of the features of thermodynamic second-order transitions. They occur in amorphous regions and involve a change in some feature of the structure from rigidity to mobility. Rigidity, which causes the material to be glassy, can come either from stiff chains or from strong interactions between chains; either of these will prevent relative movement. In a simple polymer, a single transition will occur from a rigid glass to a flexible, rubbery form; however, in some important fibers, the total change is divided

between multiple transitions. These transitions cause a major reduction in fiber stiffness, and cooling through the transition gives a temporary set.

Mobility can also be induced by plasticization; this is particularly important in moisture-absorbing fibers, where the transition temperature becomes much lower in the wet state.

Another form of minor but first-order transition, which occurs in some fibers, is between different crystal lattices.

2.5. Intermediate Structures

Some textile fibers contain structural entities at a scale immediately above the fine structure. Thus in cotton, which is a unicellular fiber, the fibrils are arranged in lamellar layers; and in wool, the microfibrils of the basic structure are grouped in macrofibrils within the individual cells which make up the whole fiber. Similar macrofibrillar associations may be present in man-made fibers, but they are not well defined and their reality has not been established conclusively. The fibrillar strands, which are often seen when fibers are pulled apart, may merely reflect lines of weakness within the fine structure.

Spherulites. The slow crystallization of polymers in bulk from the melt usually gives a spherulitic structure as a result of repeated branching from widely spaced nuclei, but the rapid cooling of fibers normally leads to a high concentration of nuclei which leaves no room for spherulites to develop. However, certain cooling patterns do allow time for some spherulite growth to start on a few heterogeneous nuclei that are stable at a higher temperature. These spherulites will grow to a certain size, but as the temperature falls, the spherulite growth will slow down and many more nuclei will be available for the final slow crystallization into a typical micellar fine structure. The spherulites will be left as occlusions within the fiber and, on drawing, will be transformed from a spherical form to a cigar-shaped ellipsoid. Generally, the conditions of fiber formation are adjusted to avoid this, but it does sometimes occur and can even be beneficial in some applications as a result of particular forms of light scattering.

Voids. In spinning from solution, coagulation commonly occurs before the solvent has been removed completely from the fiber. The material precipitates in a spongy form containing voids filled with solvent. In subsequent processing, these voids collapse as solvent dries off, and they become elongated as the fiber is stretched. The void surfaces seem to disappear to give a solid fiber, but a vestigial effect will remain with the fiber divided into fibrillar zones separated by weaker divisions. This can show up in ease of fibrillation and in a granular surface in tensile fracture.

Cells. Some natural fibres, such as wool and plant fibres like flax, but not cotton, which is a single plant cell, are multicellular. They are formed by the growth of separate cells, which are held together by chemical or physical interactions. Between the cells of wool, there is a cell membrane complex containing lipids and proteins.

2.6. Gross Inhomogeneities

Some man-made fibers have essentially the same structure over their whole cross section, but many textile fibers contain major sub-divisions. A clear example is wool, illustrated schematically in Figure 17, in which the core is bisected into two components having different chemical structure and physical fine structure, with a third form of structure present in the surface layer. Such effects in natural fibers derive from genetic control.

Figure 17. Schematic view of subdivisions of wool fiber: ortho-cortex (O), para-cortex (C), and surface scales (S)

In the less deterministic and faster industrial production of fibers, differences between skin

A), B) Side-by-side; C) Sheath-core; D) Islands-in-a-sea

and core are hard to avoid, since they experience differences in cooling, in evaporation or coagulation (if spun from solution), in nucleation, and in stresses. The patterns of crystallization are consequently different. Where molecules or crystal lattices are asymmetric in cross section, with a flat ribbonlike form which may be due to cyclic groups, the orientation within the cross section can be random, radial, or circumferential as indicated in Figure 18.

Man-made fibers can be deliberately produced as multicomponent, usually bicomponent, forms. Side-by-side fibers (Figs. 19 A and B) will develop crimp as a result of differential shrinkage. Sheath-core fibers (Fig. 19 C) are used when some special feature, such as bonding on heating, is required in the surface layer. The islands-in-a-sea fibers (Fig. 19 D) are used to make very fine fibers by removal of the matrix.

2.7. Fiber Shape

2.7.1. Cross-sectional Shape

The largest scale structural feature of a fiber is its shape. In natural fibers, this can be specialized as a result of the genetic control of growth. However, if a fiber is melt-spun by extrusion through a circular orifice, it will have a simple circular cross section. In spinning from solution, the volume reduction usually modifies the cross section. First, solidification occurs on the outside of the fiber; then the skin has to collapse as solvent is lost from the interior. Various degrees of modification are illustrated in Fig. 20. The circular form occurs when there is no loss of volume or when the chemistry of the solidification process is controlled so that it occurs uniformly throughout the fiber. When a skin forms first and a subsequent small reduction in volume occurs, a dog-bone cross section will result; but when there is a large volume reduction, highly serrated forms are produced.

Figure 20. Increasing modification of fiber shape
A) Circular (unmodified); B) Dog bone; C) Serrated

Modification of fiber shape is often desirable to change the luster or other properties of a fiber. This can be achieved in melt spinning by extruding through noncircular orifices and ensuring that solidification occurs before the fiber reverts to the equilibrium circular form. For example, extrusion through a triangular hole will lead to a rounded, three-sided shape, as suggested in Figure 21 A; but extrusion through a Y-shaped orifice will give a higher degree of modification of shape, as in Figure 21 B. The shape of the fiber can be controlled, within limits, by altering the shape of the hole and by adjusting the balance during the cooling of the molten fiber between surface tension, which favors a circular form, and viscosity, which resists change of shape. Octalobal, star-shaped fibers are another common form produced in this way.

Greater bulk can be achieved in fibers by making them hollow.

Figure 21. Fiber shape modification
A) Moderate shape modification with a triangular hole; B) Greater modification with a Y-shaped hole

2.7.2. Axial Shape

Most natural fibers have a natural *crimp*, namely, a waviness in axial shape, which is beneficial in textile processing and gives bulk, warmth, and softness to the final product. In cotton, the crimp is at a low level and somewhat irregular, but wool has a pronounced helical crimp like a spring. Simple industrial production of fibers will give straight fibers without crimp, which has to be introduced for many applications.

For some markets, the need for high crimp justifies the expense of *bicomponent fiber* production. Differential shrinkage then causes the fiber to develop curvature, as indicated in Figure 22 A. The preferred lowest energy form for the fiber would be a tight coil, shown in Figure 22 B; but axial restraint would cause this to open into an extended coil (Fig. 22 C). However, torsional restraint is also present. In order to coil up, as in Figures 22 B and 22 C, the end of the fiber would have to rotate. Since such twisting is not possible in a long continuous fiber length, the system accommodates by going into alternating left-handed and right-handed helices, as shown in Figure 22 D. The typical form of filaments in a bicomponent crimped product consists of short sections of helical crimp in opposite directions joined by reversals.

Figure 22. Crimp development resulting from differential shrinkage in a bicomponent fiber
A) Preferred crimp curvature; B) Minimum energy coiled form; C) Extended coil; D) The real form, namely, alternating helices

Texturing. Simple multifilament or monofilament yarns can be used in some applications, as dense, lustrous, silky fabrics, with the filaments remaining straight and without crimp. However, a substantial part of the textile industry is devoted to changing the axial shape

by texturing [58]. In one technique applicable to any type of multifilament yarn, the inherent fiber shape is not changed, but *projecting loops* are formed and trapped within a twisted or interlaced yarn structure. All other techniques involve heat-setting thermoplastic filaments, such as nylon and polyester, in contorted shapes. The dominant techniques are *false-twist texturing* for fine textile yarns and *jet-screen bulking* for coarse carpet yarns. *Stuffer-box, knit – deknit*, and *edge crimping* are among the other methods that have been tried.

In *twist texturing*, the yarn is set in a highly twisted state (Fig. 23 A) and then untwisted (Fig. 23 B). The filaments thus have a natural helical shape and are also under torsional stresses. When the untwisted yarn is allowed to contract by 10 – 20 % (Fig. 23 C), the internal stresses are relieved by the filaments' forming alternating helices, which can be stabilized by a second heat-setting step if a yarn with high bulk but low stretch is needed. A single-heater process gives high-stretch yarn in which the filaments contract to highly snarled forms in order to relieve torque (Fig. 23 D).

In the *jet-screen process*, the yarn is fed into a turbulent steam jet and then impacted on a screen where it is heated and cooled in order to set the filaments in complex buckled forms.

In the manufacture of man-made fibers intended for staple yarns, the tows are normally crimped before being cut into short fibers. One method involved passing the hot tow between intermeshing gear wheels, so that the filaments were set in an axial shape by the serrations. In stuffer-box crimping in which the tow is forced into a confined space that causes the filaments to buckle into a tight zigzag form; this leads to a planar sawtooth crimp.

3. Particular Textile Fibers

Although other articles in this encyclopedia deal in detail with different types of industrial fibers (→ Fibers, 4. Synthetic Organic; → Fibers, 5. Synthetic Inorganic; → Cellulose; → Wool), the preceding sections clearly demonstrate the great diversity of structure even within the limited group of general-purpose textile fibers. Consequently, to avoid leaving the subject of fiber structure in a state of uncertainty, the structure of specific materials should be summarized briefly.

3.1. Cellulosic Fibers

3.1.1. Chemistry

The repeat unit of the cellulose molecule is shown below, although the possibility that occasional groups might have a different form (i.e., be derived from a different monosaccharide) cannot be eliminated.

Cellulose [9004–34–6]

The molecule is ribbon shaped but, because of the oxygen (−O−) links, has some flexibility, at least for bending in one plane and twisting. The hydroxyl (−OH) groups readily form hydrogen bonds, which give a relatively strong attraction between neighboring chains and also lead to water absorption. In natural cellulose, the degree of polymerization is very high, but it is much less in regenerated cellulose.

A point of specialized interest is that the chain is directional, as a result of the asymmetry of the ring structure. Crystallization can occur in different forms, and controversy has existed about the precise crystal lattices. The belief now is that cellulose I, which is the usual form in natural cellulose, has all the chains aligned in the same direction (i.e., parallel), whereas cellulose II, which is formed on mercerization with caustic soda and is also the usual form in regenerated cellulose, has neighboring chains in opposite directions (i.e., antiparallel). Cellulose III and IV occur after special treatments.

The relatively stiff chain and the strong hydrogen bonding mean that dry cellulose has a high second-order transition temperature. Indeed, this temperature is above 200 °C, where measurement is not possible because the fiber chars. However, the absorption of water results in mobility, and in the wet state, the transition temperature is below room temperature. Wetting

and drying thus constitute a mechanism for setting.

In cellulose triacetate, the $-OH$ groups are replaced by acetate ($-OCOCH_3$) groups. For the more common secondary cellulose acetate, about one-sixth of the acetate groups are more or less randomly hydrolyzed back to hydroxyl groups.

3.1.2. Cotton

Cotton [39] is a unicellular fiber in which an outer primary wall first grows out from the seed coat to the final dimensions of the cotton fiber and then is filled in with a secondary wall. Cellulose is synthesized within the cell plasma by the addition of glucose molecules to growing chain molecules via an enzyme complex. About 30 molecules grow together and naturally form crystalline fibrils with chains in the parallel array of cellulose I. At the level of fine structure, the best model is an assembly of microfibrils, with the disorder coming from a lack of register in packing the fibrils together, and the density reduced by some space between fibrils. The equivalent crystallinity is about two-thirds. One unanswered question is what causes the fibrils to retain a clear identity instead of coalescing into larger crystals. Beyond the fine structure is a rich complexity of structural detail.

Figure 24. Schematic of major features of cotton structure
a) Primary wall; b) Secondary wall; c) Lumen; d) Molecule; e) Crystal lattice; f) Fibrils; g) Reversal

The thin primary wall forms with the fibrils wound in a specific array, but the structure is dominated by the thick secondary wall. The development of structure is shown schematically in Figure 24. The fibrils form lamellar sheets that wind around the inside of the cylinder at an angle which changes slightly through the thickness, but is about 21 °. At intervals, the helices reverse from right-handed (*Z*) to left-handed (*S*). Daily growth rings are apparent.

The structure at all levels is important in determining the properties of cotton fibers. Thus, moisture absorption, swelling, and accessibility to dyes occur on and between the fibril surfaces. The stress-strain curve can be explained as a deformation of the crystal lattice, with the modulus reduced by a factor approximating $\cos^4 \theta$, resulting from the helix angle θ, and additional extension occurring because of rotation at the reversals and the straightening out of gross convolutions [15].

3.1.3. Other Plant Fibers

Other plant fibers, such as flax, jute, and ramie, which stiffen stems, and sisal, which stiffens leaves, are multicellular and may contain more non-cellulosic impurities [37]. The fibrillar model of fine structure is applicable, but the geometry of arrangement in the cells is different. Usually, the helix angle is smaller, around 10 °, so that the fiber modulus is higher than in cotton.

3.1.4. Rayon

Cellulose fibers can be regenerated through several solvent systems, and these do produce structural differences [33]. The most important process is the viscose process in which a solution of sodium cellulose xanthate ($-$OH replaced by $-OCSS^-Na^+$) in caustic soda is extruded into an acid bath. Viscose rayon is of considerable structural interest because control of the chemistry of regeneration enables fibers with different structure, properties, and uses to be made. Figure 25 gives a schematic indication of the differences.

The degree of order in regenerated cellulose is about half that in natural plant fibers, with a crystallinity of about one-third. In most forms, the fine structure is assumed to be fringed micellar. The addition of zinc ions to the acid bath gives improved properties. Two regeneration routes then occur. On the surface of the fiber, the zinc salt forms first, followed by reaction with the acid to give cellulose. This yields a fine micellar texture, with small crystallites well-linked by tie molecules, which has good strength. The zinc ions do not reach the core fast enough to prevent the direct regeneration of cellulose from the sodium salt. The resulting structure is coarser in texture with larger crystals further apart, which results in a larger proportion of free ends to links, and greater stress concentrations; consequently, it is generally weaker. The collapse of the skin leads to a highly serrated cross section, with the ribbonlike molecules and crystals forced into a transverse orientation that is locally perpendicular to the surface. This is the common form of *textile viscose rayon.*

When the zinc concentration in the bath is increased and additives are included in the viscose solution that slow down the direct regeneration reaction, the whole fiber can be forced into the strong, finer textured structure. This, together with some attention to degree of polymerization and the elimination of a low molecular mass fraction, is the basis for the *high-tenacity tire-cord rayons.* The more uniform coagulation also replaces the serrated cross section by a roughly circular cross section.

Selection of other additives causes the fiber to burst open after forming a skin. This gives a bicomponent fiber with a thicker skin on one side than on the other. Such fibers naturally crimp on drying. The best *carpet fibers* combine some aspects of the high-tenacity route with the crimped route.

In all these processes, the coagulation results from the regeneration of cellulose, which crystallizes into an unoriented fiber. This is then stretched to promote orientation, to a greater extent in industrial fibers than in fibers for clothing.

When the viscose solution is extruded into a weak acid bath, such as sodium dihydrogen phosphate, the sequence changes by first coagulating a fiber of the sodium cellulose xanthate, then orienting it by stretching, and finally regenerating the cellulose. This gives the so-called *polynosic* or *high wet-modulus rayons*, which are more cottonlike in character. Crystallization

Figure 25. Schematic of routes to different types of viscose rayon

occurs in what is already a solid, oriented fiber, and this results in a fibrillar structure. The fibrils are not as well defined as in natural fibers; they consist of long crystalline units, with molecules fringing off into amorphous regions.

The late 20th century led to another means of spinning regenerated cellulose fibers, which is more environmentally acceptable. *Lyocell* fibers are high-DP cellulose fibers spun from solution in an amine oxide. They also have a fibrillar fine structure (→ Cellulose, Chap. 3.2).

Table 3 gives a comparative summary of the various cellulose fibers in terms of important structural parameters.

3.1.5. Acetate Fibers

Because of their irregular chemical structure, secondary acetate fibers are very poorly crystalline. This shows up in a low softening temperature, low resistance to extension, poor recovery, and low strength. Indeed, this oriented but almost amorphous structure gives properties which would now be inadequate to launch a new fiber, although acetate remains in markets established earlier.

Triacetate is more crystalline and is somewhat similar to fibers like nylon and polyester, although it has a lower melting point and is weaker. The structure is assumed to be micellar.

3.2. Protein Fibers

The repeat unit in proteins is an amino acid residue:

Protein

Diversity results from the selection of a particular sequence of side groups (R) from the usual 20 different types, including two which depart from the form shown in the formula. Proline, a ring of three $-CH_2-$ groups joined to the nitrogen atom in place of hydrogen. Cystine, $-CH_2SSCH_2-$, which is a bifunctional group linking two protein chains together, is produced by the cross-linking of cysteine, in which R is $-CH_2-SH$.

Keratin — a generic name for the material in wool, hair, and other appendages — is a complex mixture of different proteins with significant amounts of all types of side groups. Current understanding identifies a limited number

Table 3. Estimated relative values of structural parameters in cellulose fibers

	Degree of order	Localization of order	Aspect ratio	Orientation	Size	Molecular extent
Cotton	high	high	high	medium	fine	high
Flax	high	high	high	high	fine	high
Ordinary rayon						
core	low	medium	low	medium	coarse	low
skin	low	medium	low	medium	fine	low
High-tenacity rayon	low	medium	low	high	fine	medium
High-modulus rayon	low	medium	high	medium	fine	medium
Lyocell	low	medium	high	medium	fine	medium

of proteins making up keratin intermediate filaments (microfibrils) and a large number of keratin-associated proteins in the matrix [36, p. 72].

Silk fibroin, which contains no cystine, is a simpler protein and a natural block copolymer with sections limited to a regular sequence of residues with the side groups $-H$, $-CH_3$, and $-CH_2OH$, and other sections with more diversity, including substantial amounts of tyrosine, $-CH_2-4\text{-}C_6H_4OH$.

Proteins of the type found in fibers exhibit two different forms of crystal lattice. The α-form, a perturbation of Pauling's simple α-helix, is a coiled form with about 3.6 amino acid residues per turn. The lattice is stabilized by hydrogen bonds and other interactions between coils in the same chain. The β-form is an extended chain lattice, with hydrogen bonds between neighboring molecules.

The matrix of wool and hair is formed from globular proteins with two main families. One family of high-sulfur proteins is rich in cysteine, which is cross-linked to cystine during the keratinization stage in the growth of hair fibers. The other family consists of high tyrosine/glycine proteins.

3.2.1. Wool and Hair

Wool [36] and other hair fibers [35] show a series of structural features at various levels up to the full-scale fiber, as indicated in Figure 26.

The fine structure consists of crystalline microfibrils, composed of low-sulfur protein (without cystine), parallel to the fiber axis. This is embedded in a rubbery matrix, which is cross-linked by cystine and connected to the fibrils by tails of the low-sulfur molecules. Figure 27 shows the tensile stress – strain curve of a uniform wool fiber in the wet state. The crystal lattice is normally a coiled chain α-helix; under tension it can transform with 80 % extension to an extended chain β-lattice. The interaction with the matrix in the composite system leads to the flat yield region in the stress – strain curve, the stiffer post-yield region, and the characteristic recovery curve [59, 60].

Figure 27. Stress – strain curve of wool

The larger scale macrofibril and cell structures do not have much influence on the properties, but there may be slippage due to debonding at the lipid-rich cell membrane complex between individual cells. However, the division of the main part of the fiber, called the cortex, into an ortho-cortex, with less cystine, and a para-cortex, with more cystine, gives a bicomponent fiber. The microfibrils in the macrofibrils of the para-cortex are parallel to the fiber axis, but in the ortho-cortex the macrofibrils consist of helical assemblies of microfibrils [44]. On drying, the ortho-cortex macrofibrils tend to increase in length, due to the decrease in helix angle as the macrofibril diameter reduces, but the para-cortex macrofibrils tend to remain constant in length. The differential length change leads to a helical crimp, if the components are side-by-side, but a straight fiber if they are symmetrically distributed [61, 62]. A total model proposed for the structural mechanics of wool and hair fibers covers eight levels between molecules and the whole fiber [63].

The scale cells on the surface, with an escarpment facing the tip of the fiber, cause directional friction.

3.2.2. Silk

Silk [35], which does not form as a living cell but is an excretion, presumably evolved into a tough fiber; this would result from a crystallization of the regular sections linked in a rubbery matrix by the less regular sections. The chemical constitution would control the fine structure in a fiber which coagulates after extrusion, to form two triangular filaments held together by gum (→ Silk).

3.2.3. Regenerated Protein Fibers

Fibers have been made from the proteins in milk (casein), corn (zein), and other natural products. Generally, these fibers have a poorly ordered structure with a weakness that has led to a lack of commercial success.

3.3. Major Melt-Spun Fibers

3.3.1. Chemistry

The most important melt-spun fibers [38], dating from the middle of the 20th century, are the polyamides *nylon 66* and *nylon 6*, and the polyester *poly(ethylene terephthalate)* (PET),

with the following repeating units (see also → Fibers, 4. Synthetic Organic, Chap. 1):

Nylon 66 [*25038-54-4*]

Nylon 6 (two repeats) [*32131-17-2*]

Poly (ethylene terephthalate) (PET) [*25038-59-9*]

More recently, the commercially available syntheses of poly(trimethyleneterephthalate) (3GT) and poly(ethylenenaphthalate) (PEN) have led to the production of these polymers as textile fibers.

Little difference exists between the two polyamides: in contrast to nylon 66, nylon 6 has five and five $-CH_2-$ groups, instead of four and six; has the middle $-CONH-$ group reversed to $-NHCO-$; and consequently, has only half the length of repeat unit. Perhaps the most important feature is that the nylon 6 molecule is directional, so neighboring chains in a crystal must be in proper relation to each other. This might be the reason nylon 6 melts at a temperature ca. 50 °C lower than nylon 66 and PET.

All three polymers have a very long repeating unit, which gives fewer choices of location in crystals than in simpler polymers such as polyethylene, and thus leads to lower maximum crystallinities. The other common characteristic is the presence of a flexible aliphatic sequence with weak interactions. In between these sequences, the polyamides have $-CONH-$ groups which interact by hydrogen bonding, and polyester has benzene rings which are both stiff and interactive.

The crystal lattices of these polymers are simple extended chain forms and are known. In nylon 6, some complications result from the existence of two alternative forms.

The glass-to-rubber transition in nylon and polyester occurs in two stages, which is a valuable feature. A transition below room temperature gives a measure of extensibility and toughness to the fiber, while sufficient stiffness is retained. The remaining inevitable transition to a fully rubbery, amorphous form between crystallites occurs at a higher temperature. The first transition is associated with the onset of mobility in rotation around $-CH_2-$ and similar bonds in the aliphatic sequences. In nylon, the second transition is associated with the hydrogen bonds moving into a state of dynamic equilibrium, so that the chain segments in amorphous regions become completely free. This transition temperature is much lower in wet fibers. In polyester, analogous interactions of the benzene rings occur, but the transition temperature is somewhat higher and is little affected by water. The benzene rings lead to a higher initial modulus in PET than in nylon. 3GT with more aliphatic groups is more like nylon, but the double ring in PEN leads to a stiffer fiber with a higher melting-point.

Another major melt-spun fiber is *isotactic polypropylene* [*9003-07-0*], $\text{+}CH_2CH(CH_3)\text{+}_n$. Because of the bulky side group, the molecule forms a threefold helical coil, which gives it a greater stiffness in the melt or in amorphous regions, but a lower axial modulus in the crystal. Polypropylene has a single broad glass transition near room temperature.

3.3.2. Fine Structure

Despite their major importance as industrial products for about 50 years, surprisingly little is known about the fine structure of melt-spun fibers. The degree of order corresponds to a crystallinity of about 50 %, not much changed by differences in processing. The degree of orientation can be controlled within fairly wide limits by the speed of windup, subsequent drawing, and hot-stretching or relaxing treatment.

As a working model, the structure is assumed to consist of crystalline micelles, partly folded and partly fringed at the ends, and linked by tie molecules. The crystallites are assumed to be stacked in pseudofibrils, as shown in Figure 5. Some authors have suggested significant differences between amorphous material joining crystallites within a pseudofibril and amor-

phous material separating pseudofibrils. However, good quantitative information is lacking about the size and shape of crystallites, their arrangement in some form of superlattice, the relative amount of folds and tie molecules, and the detailed pattern of interconnections between crystallites. Evidence exists that annealing treatment leads to the development of larger crystallites spaced farther apart. If the fiber is free to contract, chain folding may develop.

Consideration of the change in endotherms observed in differential scanning calorimetry indicates that rapid "crystallization" leads to a form I. This has been suggested [56] to be a more uniform structure (see Fig. 9), with small neighboring segments in crystallographic register, but in dynamic equilibrium just below the almost constant melting point observed for form I. Annealing then leads to the formation of small separate crystallites, initially with a lower melting point but a lower free energy at the annealing temperature. Prolonged annealing increases the size and perfection of the crystallites, and raises the melting point.

Despite many similarities, nylon and polyester have significant differences. Cooling of an unoriented fiber, being wound up at a low speed such as 1000 m/min (ca. 20 m/s), leads to crystallization in nylon but not in polyester. Only the subsequent drawing causes the polyester to crystallize. Textile polyester fibers have a higher initial modulus than nylon and split axially at an angle closer to the fiber axis. These differences are presumably associated with the stiffness of the benzene ring, but the structural implications are not understood in detail.

When polyester fibers are wound at a higher speed, around 3000 m/min (ca. 50 m/s), they develop an incipient crystallinity that makes them more stable and easier to process. These are the so-called partially oriented yarns (POY) used as draw-texturing feed yarns. At still higher speeds, sufficient orientation and crystallinity can be induced to give fibers suitable for some applications without drawing. However, the degree of orientation that can be achieved this way is lower than in the two-stage route. The fine structure is also different and seems to contain larger crystallites.

3.3.3. PLA Fibers

The newest melt-spun fiber is PLA [64], which is produced with the tradename NatureWorks. There is less structural information available on this type of fiber. It can be assumed that it is a poly(lactic acid) fiber, which has an ester linkage between the −OH and −COOH groups at opposite ends of the lactic acid molecule. The basic chemical formula is:

The US Federal Trade Commission definition issued in 2002 states that there must be at least 85 % of lactic acid ester units in the chain, but includes poly(lactate)s, which could contain other units. For example, there could be copolymerisation with ethylene terephthalate or other groups.

3.4. Acrylic Fibers

The remaining major synthetic fiber type has acrylonitrile, $-CH_2CH(CN)-$, as its principal repeating unit [38] (see → Fibers, 4. Synthetic Organic, Chap. 5). However, for dyeability, up to 15 % of a comonomer must be included. Suggestions abound in the patent literature, along with a diversity of practice by manufacturers, about both the type of comonomer and the form of copolymerization. The degree of tacticity of the polyacrylonitrile [*25014-41-9*] is also not well documented but probably atactic. Because of these features, acrylic fibers are rather different in structure from most other types.

The molecule appears to act as a cylindrical rod with strong, but not very localized, attractive forces coming from the dipole in the $-C{\equiv}N$ group. The rods pack regularly side by side, like chalk in a box, but are not in register along their length. The fine structure is thus assumed to consist of such ordered pseudocrystalline regions mixed with less ordered regions. A big second-order transition occurs around 100 °C, when the segments in the less ordered regions overcome the interactions and can slide over one another easily; other transitions then take place,

at higher temperatures, until the structure decomposes while still solid.

3.5. Other Polymers

Other linear polymers have been used to a limited extent in textile fibers. Their fine structures have usually not been studied in detail but are similar to the most nearly corresponding major fibers. Among melt-spun fibers there has been some production of other variant *polyamides* and *polyesters*. Some of these, such as nylon 4 and poly(butylene terephthalate), differ only in the length of $-CH_2-$ sequences. Qiana (Du Pont), marketed as a luxury fashion fiber but no longer made, was a more complicated polyamide.

Polyethylene [*9002-88-4*], $\text{+}CH_2-CH_2\text{+}_n$, fibers are spun from the melt or, in the spunbonded material Tyvek (Du Pont), are flash-spun from solution to give a fibrous network. The structure is highly crystalline, probably with the lamellar form characteristic of crystallization in this polymer; disorder would then arise from the localized defects possible with such a small repeat unit (see → Fibers, 4. Synthetic Organic, and Section 4.2.2). High-modulus polyethylene is dealt with in Chapter 4.

Poly(vinyl chloride) [*9002-86-2*], PVC, $[CH_2CH(Cl)]_n$, is similar to acrylic fibers, as are other vinyl and vinylidene copolymers with chlorine, acetate, or other side groups (see → Fibers, 4. Synthetic Organic, Chap. 6).

Poly(vinyl alcohol) [*9002-89-5*], PVA, $[CH_2CH(OH)]_n$, has special features associated with hydrogen bonding of $-OH$ groups. In one form, the attraction for water leads to solution on washing, but this can be eliminated by appropriate treatment. Full information on PVA fibers is given in [65] (see also → Fibers, 4. Synthetic Organic, Chap. 7).

4. High-Modulus, High-Tenacity Fibers

An important, new generation of fibers has appeared, intended for engineering use either in flexible systems (e.g., ropes and other tension members), in special tires or in rigid composites, and characterized by high stiffness and high strength. Most of these fibers also show high temperature and chemical resistance, and some fibers selected mainly for thermal stability have high stiffness even if not high strength. The choice of category is thus sometimes rather arbitrary, but this section includes fibers selected mainly for mechanical performance, while Section 5.4 includes those selected mainly for thermal and chemical stability. The strong fibers are reviewed in [34, 66].

The advantages of using a material in fiber form are discussed in Section 1.1, but in some cases the structure of the fiber material differs little from other forms of the material. In these cases, only brief comments will be given in this article, and reference should be made to other articles in this encyclopedia for more general and detailed information on structure (→ High-Performance Fibers).

4.1. Glass

The structure of glass fibers is essentially the same as the structure of bulk glass [34, pp. 191–238]. Solidification from the molten state gives an isotropic three-dimensional network based on a tetrahedron of four oxygen atoms around a silicon atom, but made irregular and amorphous by metal ions. A typical composition of E-glass fiber intended for electrical insulation is 52 – 56 % silicon dioxide, 16 – 25 % calcium oxide, 12 – 16 % aluminum oxide, 8 – 13 % boron oxide, 0 – 1 % sodium and potassium oxides, and 0 – 6 % magnesium oxide. Different compositions are used in the newer glass fibers optimized for other markets; for example, the high-strength S-2 glass fiber is low in alkali and high in magnesium. Glass fibers are reviewed in [67] and [68]; see → Fibers, 5. Synthetic Inorganic.

4.2. Highly Oriented Linear Polymers

High-tenacity, high-modulus polymer fibers have a structure that satisfies the three requirements of high order, high orientation and — most important — high molecular extent. In practice, such a structure can be reached only by specialized routes, and this has not been achieved with such common polymers as nylon and polyester (PET). There are two main production methods. The first route requires very stiff

and strongly interactive molecular chains, which inhibit chain folding. In most cases, this group of fibers depends on orientation during extrusion of a liquid crystal solution or melt. The second route involves a "combing out" of the chain molecules by some means such as gel spinning or super-drawing and requires very flexible and weakly interactive molecules.

4.2.1. Aramid

The first high-tenacity aramid fiber was introduced by Du Pont with the name *Kevlar*; other manufacturers now also produce aramid fibers [34, pp. 23–61]. It is composed of poly(*p*-phenylene terephthalamide) (PPTA)

a stiff, rodlike molecule with strong hydrogen-bonding interactions at the −CONH− groups and electronic interaction between benzene rings. In solution, the molecule forms liquid crystals which are easily oriented on extrusion. The resulting fiber has a structure that is very highly oriented and highly crystalline. The molecules are fully extended. The crystal perfection persists only for limited distances, with a packing pattern derived from the rodlike liquid crystals. Suggestions have been made of the occurrence of pleated sheets arranged radially in the structure. However, specialized articles should be consulted for such details [69, 70], (→ High-Performance Fibers).

Teijin produces another aramid fiber called *Technora* [71], but this is a copolyterephthalamide of *p*-phenylenediamine and 4,4′-diaminodiphenyl ether, and is a 50 mol % copolymer of

and

Evidence exists for the presence of the crystal structures of both homopolymers. In contrast to PPTA fibers, the highly-oriented, chain-extended structure is not formed from a liquid-crystal solution, but results from drawing and heat-treating of fiber coagulated from an extruded isotropic solution.

Other aramid and related aromatic fibers with similar structures have been produced in Russia [34, pp. 115–132].

4.2.2. Polyethylene

Polyethylene, which has the simple $-CH_2-$ repeat unit, can be produced as a high-strength, high-modulus fiber that is highly crystalline and highly oriented, and has the molecules highly extended with a minimum of chain folding. The polymer will always be linear, but the degree of polymerization depends on the production method.

The highest strength and stiffness is produced by gel spinning from a fairly concentrated solution of ultrahigh molecular mass polymer, which allows for a high degree of subsequent elongation [34, pp. 62–92]. Melt-spinning and super-drawing is a cheaper process but requires lower molecular mass, so that the resulting properties are not as good. Solid-state extrusion of a crystal mat is another method of achieving the required structure [34, pp. 132–144]. Three reviews give many details [72 – 74]; see also → Fibers, 4. Synthetic Organic.

4.2.3. Other Polymers

Several other fiber types are produced by the liquid-crystal route.

Vectran, which is melt-spun and then heat-treated to increase molecular mass, is a fully aromatic co-polyester with the formula:

Other research, aimed at superior properties rather than lower cost, is utilizing some newly synthesized materials such as stiff-chain aromatic heterocyclic polymers (with the general designation PBZ) based on benzothiazole (PBS)

or benzoxazole (PBO) ring structures. Typical repeat units are

PBS [95-16-9]

PBO [273-53-0]

PBO is now commercialized as *Zylon* [34, pp. 101–108]. Although the molecules of these fibers are highly oriented and packed side by side in a regular array, they are not necessarily in crystallographic register along their length.

Aramid and PBO fibers have relatively weak intermolecular bonding and consequently have low shear resistance and fail in compressing by internal buckling. Sikkema [34, pp. 108–115], [75] has synthesized the new polymer M5, which is made from tetraaminopyridine and dihydroxyterephthalic acid, and prepared experimental fibers. Projecting OH groups lead to hydrogen bonding in both directions, as distinct from the planar hydrogen bonding in the para-aramid fiber, with a resulting improvement in shear and compression resistance in fibers. The chemical formula is:

There have been reports on studies of poly(vinyl alcohol) fibers produced by gel spinning or superdrawing, and other materials are being investigated.

A third special route has been applied to polydiacetylenes, which have the following general formula:

where R represents a large number of possible side groups.

Single-whisker crystals of the precursor diacetylene can be grown, which is then polymerized in the solid state. The resulting fiber is essentially a perfect polymer single crystal.

Another route that has been applied to polyethylene, is virgin polymerization in which the orientation, crystallinity, and molecular extent are established at a point of polymerization of chains.

4.3. Carbon Fibers

When a suitable organic precursor fiber is subjected to a sequence of heat treatments, ending with a very high temperature under tension, a high-modulus carbon fiber is produced with a quasi-graphitic structure [34, pp. 156–190]. Depending on the starting material, usually polyacryonitrile fibers or pitch fibers, and the details of the heat treatments, considerable variations in structure occur, which lead to a range of combinations of strength and stiffness.

Pure graphite crystals consist of a stack of planar sheets of carbon atoms in a hexagonal array. Most carbon fibers are turbostratic, with neighboring parallel sheets not in crystallographic register. However, any assembly of parallel sheets would be useless in fibers due to lack of lateral cohesion, which leads to the use of graphite as a lubricant. Some disorder, which links sheets, is needed. Carbon fibers are a disturbed and distorted assembly of graphitic crystalline elements, for which many different pictures have been drawn. The sheets are arranged in separate layers that are bent and folded within the structure. It seems likely that the conversion of the original linear polymers into two-dimensional sheets may have developed in different regions, which leads to occasional cross-linking C−C bonds between neighboring portions of sheets to give a sparse three-dimensional network. An important feature for high modulus is that the planes should all be aligned closely parallel to the fiber axis. This still leaves two degrees of freedom of local orientation of a plane. Rotation about axes perpendicular to the plane allows neighboring planes to be at different angles in a turbostratic structure. Rotation of the planes around a line parallel to the fiber axis, which must occur cooperatively between neighboring sheets to maintain close packing, allows for a variety of transverse orientations within carbon fibers. Radial, circumferential and other patterns occur.

Carbon fibers are dealt with in several chapters in [66], as well as in [76] and [77]; see also → Fibers, 5. Synthetic Inorganic.

4.4. Ceramic and Other Inorganic Fibers

Quartz fibers have a long history in scientific instrumentation, but the production of fine ceramic fibers with diameters of the order of 10 μm for use in high-temperature composites was first commercialised in the 1980s. Ceramic fibers, are covered in several chapters in [26, 51, 80]. The account below is based on the more recent publication [34, pp. 239–258] (see also → Fibers, 5. Synthetic Inorganic, Chap. 4).

Since the 1980s, there have been considerable development and the market has stabilized with silicon carbide based and alumina based fibers as the main types. The fibers have a structure which is typical of polycrystalline ceramics, but it has been shown that small differences in the fabrication processes lead to considerable differences in microstructure.

One group of silicon carbide based fibers (see also → Fibers, 5. Synthetic Inorganic, Chap. 3) are made by treatments of organosilicon polymer fibers. A typical *Nicalon* fiber from Nippon Carbide contains 56 % Si, 32 % C and 12 % O. β-SiC is present in grains of about 2 nm size, with the remaining 45% of the fiber composed of a metastable Si-C-O phase, which impedes grain growth and allows creep to occur, and free carbon particles. In *Hi-Nicalon* the oxygen content is reduced to 0.5 % or less but the fiber contains more free carbon. The SiC grains are 5 to 20 nm in size, surrounded by less crystalline SiC and turbostratic carbon. *Tyraano Lox* fibers from Ube Industries include about 2 % of Ti with 55 % of Si and varying amounts of C and O and have microstructures similar to the high-oxygen Nicalon *fibers*. Near-stoichometric SiC fibers, which contain more than 95 % SiC, are made by sintering processes. Grain sizes are of the order of 200 nm with pockets of free carbon between the grains.

Alumina fibers are derived from the extrusion of viscous solutions of aluminum salts, which are processed to give over 99 % Al_2O_3 fibers. Up to around 1000 °C grain sizes range from 10 to 100 nm, but above 1100 °C rapid growth of micron-sized α-alumina grains occurs and the fibers become brittle. Small grain size is maintained in alumina – silica fibers. For example, *Altex* from Sumitomo contains 15 % of SiO_2 and consists of 25 nm γ-alumina grains surrounded by amorphous silica. *Nextel* fibers from 3M contain B_2O_3 and have the composition of mullite. With 14 % B_2O_3, *Nextel* 312 is described as quasi-amorphous, but *Nextel* 440 with 2 % B_2O_3 consists of γ-alumina in silica. The presence of silica leads to more flexible fibers, which creep and lose strength above 900 °C. *Nextel* 650 is an alumina – zirconia fiber, which contains 10 % of ZrO_2 and 1 % of Y_2O_3.

Large diameter ceramic "fibers" can be made by vapor deposition on a substrate such as tungsten or carbon filament. Another type of ceramic fiber consists of monocrystalline inorganic crystal whiskers. Ceramic fibers, are covered in several chapters in [26, 66, 77]; see also → Fibers, 5. Synthetic Inorganic.

4.5. Structure and Properties

By definition, all the fibers included in this section have a *high modulus* and most have a *high strength*. Although each fiber type should be examined separately, a broad generalization is that the linear polymers give very high strength but somewhat lower modulus; that the carbon fibers can have high strength and the highest moduli; that the ceramic fibers have lower strength but high modulus; and that the amorphous structure of glass leads to lower values of both strength and modulus.

However, the structural differences cause big differences in some other properties. The highly oriented linear polymer fibers inevitably have a low *compressive yield stress*, since only weak forces exist between molecules and the chains can buckle within the fibers. They are prone to splitting into fibrils and usually break by long axial splits. By contrast, glass and ceramic fibers, which have a three-dimensionally bonded structure, and carbon, which is also coherent in all directions, show similar behavior in compression and tension. They usually break cleanly across the fiber.

Although the three-dimensional fiber structures are good in compression, the same effect causes the fibers to be poor in *flexibility* because

they snap easily. On bending, the outside is extended and the inside is compressed; the smallest radius of curvature R that can be achieved is given by $R = r/e$, where r is the fiber radius and e the fiber breaking strain. Therefore, the tightest achievable curvature is more than 20 times the fiber radius. In contrast to this, the linear polymer fibers can be bent back on themselves to nominally zero values of curvature without breaking, because yielding on the compression side allows the neutral plane to move out so that the extension on the outer surface does not exceed the fiber breaking extension. Another benefit, arising partly from this and partly from the axial splitting, is that linear polymer fibers are more effective in absorbing energy. They are the best materials for ballistic impact resistance fabrics, in which glass or carbon is useless, and generally show greater damage tolerance in structures.

The other important difference is in *thermal resistance*, which depends on chemical composition. Polyethylene melts at a low temperature, and shows excessive creep and loss of mechanical properties even at 100 °C. The aramids and the newer rigid rod polymers do not melt but decompose at around 500 °C. Glass begins to soften at similar temperatures. The ceramic and carbon fibers withstand very high temperatures.

5. Other Fibers

The two major groups of fibers are the general-purpose textile fibers, whose structure is described in Chapters 2 and 3, and the high performance engineering fibers, described in Chapter 4. However, a miscellaneous group of fibers is also used for a variety of purposes to be mentioned in this section. Generally, the main structural interest is in the chemical composition, and other structural details are either little known or similar to the most common forms of the particular material, which are discussed in other articles in this encyclopedia.

5.1. High-Toughness Fibers

Some engineering uses of fibers require high toughness, shown by a high work of rupture (energy to break, or area under stress – strain curve), usually accompanied by a fairly high modulus. The structure of these fibers is described in Section 3.3; they include the melt-spun polyamides, polyester, and polypropylene. However, the industrial yarns are processed so as to maximize the degree of orientation.

5.2. Elastomeric Fibers

The elastomeric fibers are at the opposite extreme to the high-modulus fibers. Elastomeric fibers are intended for applications in which high stretch is required; the breaking extension may be as high as 500 %, and the modulus is inevitably low.

Natural rubber, either in the form of thread cut from sheet or as extruded latex, was the first material to be used. It consisted of thick monofilaments or bundles of monofilaments. Their structure is the usual cross-linked amorphous network formed by vulcanization.

However, modern elastomeric fibers are mostly spandex fibers composed of segmented polyurethanes and able to be made in typical textile filament diameters. The polymer is an alternating block copolymer, in which "soft" segments provide the high extension by changing from coiled to extended forms, and the "hard" segments interact and form small crystalline or quasicrystalline domains to hold the structure together. The fine structure is thus an unoriented, fringed micelle form with a low degree of crystallinity (high fraction of a rubbery amorphous phase). Under low or moderate tension, the mechanism of rubber elasticity will allow high stretch by the uncoiling of soft segments, but under high tension the alignment of soft segments may lead to some crystallization that reinforces and strengthens the structure.

In contrast to natural rubber, in which chemical cross-links join chains in pairs, the clustering of connections in the hard segment domains is an important structural feature for good mechanical properties.

In principle, many possible chemical forms exist for soft and hard segments, and even with a particular choice of components the proportions may be varied. Couper [78] reports a typical monomer for a soft-segment block to be

$$\mathrm{OCN{-}[A]{-}NHCO}\left(\mathrm{{-}O{-}[B]{-}CONH{-}[A]{-}NHCO}\right)_n\mathrm{{-}O{-}[B]{-}OCONH{-}[A]{-}NCO}$$

where OCN−[A]−NCO is an aromatic diisocyanate, O−[B]−OCO is the polyether or polyester chain of a macroglycol, and n is a small number varying from molecule to molecule.

This monomer is then linked by bifunctional chain extenders, usually diamines, to the hard segments. A typical hard segment is reported to be

$$-\!\!\left(\begin{array}{l}\text{CONH}-[\text{A}]-\text{NHCO}-\text{NH}-[\text{C}]-\text{NH}\\ -\text{CONH}-[\text{A}]-\text{NHCO}\end{array}\right)\!\!-_m$$

where [C] is the aliphatic sequence in a diamine and m is an integer.

5.3. Thermally and Chemically Resistant Fibers

Apart from polyethylene, all the high-modulus, high-tenacity fibers described in Chapter 4 have good thermal and chemical resistance. This is particularly so for ceramic and carbon fibers. However, other fibers, some of which have only moderate or poor mechanical properties are used for insulation protection, filtration, chemical engineering functions, or reduction of fire hazards [34, pp. 259–324].

Asbestos, which is very brittle and now recognized to be medically dangerous, was once widely used. It is an inorganic mineral of structural interest because its fibrous form derives from the fact that the unit cell of the crystal is naturally curved in a small radius. The crystals grow by forming cylinders of many layers of rolled-up sheets, limited by the extent of allowable distortion as the inner and outer radii depart from the preferred value. The space in the center of the cylinder and between cylinders is filled with secondary crystallization, in which the cylinders are incomplete (→ Asbestos).

Rock wools formed from a melt dispersed into fiber form have a polycrystalline structure.

Several linear organic polymers are used to make resistant fibers with reasonable textile properties. One route is to choose rather stiff chains with strong interactions, which have a high melting point and a chemical structure selected to avoid flammability and prevent decomposition at too low a temperature. One such polymer is the m-aramid, poly(m-phenylene isophthalamide) [*9016-75-5*], marketed as Nomex (Du Pont):

The shape of the chain makes it easier to form into fibers than the p-aramid, and leads to a more extensible fiber with good textile properties.

Various arimid fibers have been produced experimentally. The one that is commercially available is *P84*, which was developed by Lenzing but is now produced by Inspec Fibers. Its composition is:

where R is $C_6H_4CH_2$.

Kermel from Rhône-Poulenc is a poly(aramide-imide) fiber. The chemical structure is reported as:

A fiber with higher temperature stability and high moisture absorption, is poly[2,2′-(m-phenylene)-5,5′-bibenzimidazole] or PBI [79], with the following repeat unit:

This is stabilized by forming a salt with sulfuric acid.

The fine structures of these fibers are similar to those of other crystallizable polymers spun from solution.

If the route to carbon fibers is stopped after the first stage of treatment of acrylic fibers, thermally resistant, partially carbonized fibers are produced. The disorganized structure of *Panox* fibers leads to comparatively low strength, but textile properties which give reasonably comfortable flame-proof protection. Further heat treatment gives improved thermal resistance but greater brittleness, as shown by Curlon fibers.

If good textile properties are sacrificed, thermoset resins with a characteristic amorphous, three-dimensional, polymer network structure provide thermally resistant fibers. The novoloid fiber *Kynol* (formerly made by Carborundum now by Kynol Corporation) is a thermoset phenolic resin, with the structure being a three-dimensionally cross-linked network, typified by forms such as:

Basofil from BASF is a melamine-formaldehyde resin.

Polytetrafluoroethylene [*9002-84-0*], PTFE, is a very inert and stable polymer with the simple repeat unit $-(CF_2)-_n$. It has good chemical resistance at high temperatures. The coiling of the molecules in shallow turns stiffens the chains and leads to a high glass transition temperature and stable crystals, which show some lattice transitions. The polymer decomposes at a high temperature before it melts and is insoluble. Consequently, it must be spun from a dispersion and then consolidated by sintering, which is reflected in the structure (→ Fibers, 4. Synthetic Organic, Chap. 8).

Various other polymers with good chemical resistance can be melt-spun and would be expected to have structures similar to other melt-spun fibers; copolymers would have lower crystallinity. Poly(vinylidene chloride) (PVDC, $-CCl_2CCl_2-$) can only be spun when copolymerized with other vinyl or acrylic monomers. Fluorinated polymers, poly(vinyl fluoride), poly(vinylidene fluoride) and fluorinated ethylene polymers and copolymers are another group of materials.

PEEK, poly(etheretherketone) is melt-spun at high temperature by Zyex in a range of cross-sections and sizes. The chemical formula is:

Other polyetherketones have not proved commercially successful.

Poly(phenylene sulfide) [29] fibers are produced by a number of companies. The chemical formula is:

Poly(etherimide) fiber is another chemically resistant fiber that can be melt-spun. However, its complicated chain form brings about an amorphous structure. The chemical formula is:

5.4. Special-Purpose Fibers

Many fibers are made for a variety of special purposes, but only some brief indications of chemical and physical structure can be given. A number of these fibers are described in [27].

Fibers that dissolve in water, possibly hot or with soap or other common chemicals present, have some uses. Such fibers can be made from poly(vinyl alcohol). $\text{+CH}_2\text{CH(OH)+}_n$, or from calcium alginate derived from seaweed. A number of fibers for biomedical applications are made from linear polymers selected for their beneficial interaction with the body [81].

Many fibers are naturally absorbent, and this can be enhanced by modifying the chemical or physical structure. A particular example is the conversion to *activated carbon fibers* with many accessible microvoids. Unlike the high performance carbon fibers, those fibers have not been subjected to high-temperature graphitization.

Particular structural features may also occur on a large scale. *Hollow fibers*, made of a suitable material, can be used for chemical separation processes or the controlled release of reagents.

Metal fibers may be extremely fine-drawn wires used for special purposes, such as tungsten filaments in light bulbs or fibers for leakage of static electricity in carpets. A decoratively used fiber is *Lurex* (Sildorex), which consists of aluminum anodized to give color, cut into fine strips from foil, and laminated with plastic protection. These materials have the usual fine structure of metals. However, a special structure, which can only be found in fibers or thin films, is the amorphous structure of metallic glasses formed by rapid chilling [82]. The blocking of defect mobility leads to a very high yield stress.

Materials with special electrical or optical properties can be made in fiber form. For example, fibers with the structure of electrets are useful in filtration. The most important application in this category consists of optical fibers for communication. These are usually made of specially constituted inorganic glasses, but polymeric fibers have also been tried (→ Fiber Optics).

5.5. Nanofibers and Carbon Nanotubes

Electrospinning [9], which can be carried out on small-scale equipment, has made it possible to produce fibers with diameters down to a few nanometers. It was once thought that the fineness resulted from a splitting of the extruded fiber, but it is now known that it results from a massive attenuation of the fiber in a whirling mode. The web that is collected is a single fiber of enormous length. Spinning can be from solution or melt, so that a wide range of polymer nanofibers can be produced. The chemistry and fine structure would be expected to be similar to that of larger fibers made from the same material, though the fact that all the material is as close to the surface as the outer layer of a coarse fiber may lead to some differences.

The other type of nanofiber now in experimental production consists of carbon nanotubes. These derive from the dsicovery of C_{60}, in which carbon atoms are covalently bonded into a spherical network known as a buckyball. It was then found that hemispherical ends could be linked by a tube with a similar network. The basic structure is thus a two-dimensional, covalently bonded sheet of carbon atoms, which wraps around to form a tube. Short lengths of multiwalled tubes with diameters of 4 to 50 nm were reported in 1991 [83]. Long singlewalled carbon nanotubes with diameters of about 1.5 nm can be produced in carbon arcs [84, 85] or by laser ablation [86] and can be collected in rope form [87]. However, these methods are only suitable for producing minute amounts for scientific study or specialist uses.

The production of coarse multiwalled carbon fibers by vapor deposition had been known for over 100 years. 21st century research [5, 6] has shown that is possible to grow finer carbon nanotubes by vapor deposition and collect them as long lengths of yarn. Terminology [5] is confusing because this "yarn" is referred to as a "fiber", and not as a yarn composed of nanotube fibers. The nanotubes may be singlewalled with 1.6–3.5 nm in bundles with a diameter of 30 nm or multiwalled with diameters of 30 nm and aspect ratios of $\gg$1000:1 [5].

5.6. Smart Fibers

A major development of the 21st century is the production of smart fibers [41, 42]. Typically they are electrically, optically, mechanically, thermally, or chemically active and hence respond to external stimuli. It is beyond the scope of this chapter to go into detail on smart fibers. From a structural view point, it can be said that some fibers may be made of a single active

material, but more commonly the special properties result from inclusions or surface coatings. Two examples are the incorporation of globules of a phase-change material, which reduces the effect of changes of temperature, and coating fibers with a piezoelectric polymer, which enables fabrics to act as electric switches.

Acronyms and Symbols

BCF	bulked continuous filament
DSC	differential scanning calorimetry
FDY	fully drawn yarn
HE	highly elastic
LOY	low orientation yarn
NVC	nip-controlled vector
PES	polyester
PETP	poly(ethylene terephthalate)
POY	partially oriented yarn
RFR	ribbon-free random wind
F	degree of setting, force
G	free energy, polymer throughput per spinneret hole
K	energy of cohesion
L	maximum thread length
$m*$	mass flow rate
$\bar{M}_{\mathrm{w}}$	weight-average molecular mass
N	normal stress difference
S	entropy, shrinkage
T	titer (fineness), temperature
U	internal energy
v	velocity
v_{L}	take-up velocity
v_0	extrusion velocity
V	volume
V_{z}	spin-draw ratio
x	distance
α	countersink angle
β	angle of transition
ε	elongation
$\dot{\varepsilon}$	elongation rate
ε_{H}	Hencky measure of elongation
$\dot{\gamma}$	shear rate
θ	temperature, normal stress coefficient
η	shear (dynamic) viscosity
η_{D}	elongational viscosity
σ	tensile stress, tenacity at break (based on titer)
σ_0	tenacity based on initial fineness
σ_{s}	surface tension
σ_{t}	tenacity based on cross-sectional area
τ	shear stress, relaxation time

1. Introduction

Man-made fibers are manufactured by converting high-molecular polymer materials into continuous fibers (monofilaments, filaments, tow, or staple fibers). Monofilament is a single continous fiber, filaments are composed of a certain number of continous spun and collected single fibers, tow consists of a collection of thousands of continous filaments, and staple fibers are tow that has been cut into discrete lengths. For a general description of fibers and their properties, see → Fibers, 1. Survey.

Key process steps in fiber production are

1) Spinning
2) Drawing
3) Posttreatment

In the first of these steps, *spinning*, polymers are forced by dosing units through small capillaries, either as a melt or in solution and then solidified into fibers by cooling, precipitation, or solvent evaporation. During spinning, the macromolecular chains are only partially oriented in a preferred direction. (Spinning may also be defined to include the process in which fibers of finite length, i.e., staple fibers, are combined to form yarn; this is, however, part of a different technology and is not treated in this article.)

In the second step, *drawing*, the as-spun fibers are often stretched to many times their original length. Drawing increases the molecular orientation along the fiber axis and is frequently accompanied by an increase in crystallinity and fiber strength.

In the third step, *posttreatment*, the drawn fibers are heated under tension or under defined conditions of relaxation (heat-setting or thermosetting). If necessary, filaments, which after spinning and drawing normally have a flat characteristic, can also be textured, and tow can be crimped. Heat-setting changes the fiber morphology and allows the properties of the filament yarn, staple fibers, or tow to be adapted to end-use requirements. A finishing oil must be applied to the fibers to improve their processing properties. The proper formulation of a finishing oil requires a balanced combination of lubricating, cohesive, and antistatic properties.

The classical production of synthetic fibers involves several separate steps. New technologies have been developed in the past few years with the goal of integrating as many production steps as possible into a single continous process; this has improved both the economics of synthetic fiber manufacture and the quality of the products.

2. Theory and Mechanisms of Fiber Production

2.1. Spinning

This section deals solely with melt and solution spinning. Other spinning methods such as emulsion and suspension spinning, phase-separation spinning, reaction spinning, and interfacial, and surface spinning are described in [1], [2].

2.1.1. General Description

In all spinning processes, a spin pump continuously forces a fluid spinning mass, sometimes under considerable pressure, through a spinneret orifice (the shaping element) into a suitable liquid or gaseous medium. The resulting filament is solidified by adjusting the temperature or the concentration of the medium. The spinning mass is converted into a fluid state by melting or by dissolution, depending on the properties (thermal stability) of the raw material. If the material is neither fusible nor soluble, special spinning processes are required. As the filament leaves the spinneret, it is narrowed, while still in the fluid state, by drawing off at a constant take-up velocity. The polymer molecules become weakly oriented along the longitudinal axis of the fiber as solidification progresses. Changes in morphology may occur depending on the process used.

Characteristic Variables. An important characteristic of the spinning process is the *spin-draw ratio* V_Z which represents the ratio of the take-up velocity v_L to the extrusion velocity v_0, i.e., the speed at which the spinning mass leaves the spinneret:

$$V_Z = v_L / v_0$$

The extrusion velocity v_0 is calculated from the ratio of the volume throughput (cubic centimeters per second) to the free cross-sectional area of the spinneret holes (square centimeters); both parameters are based on either the entire spinneret plate or on only a single filament (one hole). The spin-draw ratio varies with the spinning process; in melt spinning, it may be as high as several hundred, but in solution spinning the extrusion velocity for some polymers exceeds the take-up velocity (i.e., draw ratio < 1).

The most important characteristic of the as-spun material is the titer T which is a measure of its fineness and is also called the linear density. The titer is defined as the mass per unit length (grams per meter) and is expressed in tex:

$$1\,\text{tex} = 1\,\text{g per } 1000\,\text{m}$$
$$1\,\text{dtex} = 1\,\text{g per } 10000\,\text{m}$$

By differentiating fiber mass and length with respect to time, the equation defining the fineness can be rewritten as:

$$\text{Titer} = \frac{\text{Mass flow rate (g/s)}}{\text{Take-up velocity (m/s)}}$$
$$\text{T (dtex)} = \frac{m^* \text{ (g/s)}}{v_L \text{ (m/s)}} \times 10000$$

This equation is frequently used in spinning technology. The yarn number is obtained by assuming $m*$ to be the throughput of the entire spinneret plate. To obtain the fineness of an individual filament, the yarn number is divided by the number of spinneret holes. If the spinning mass is diluted, $m*$ must be corrected appropriately to calculate the fineness. The equation shows that the as-spun fineness depends only on the spinneret throughput and the take-up velocity. The diameter of the spinneret hole (and the associated spin-draw ratio) does not affect fineness but does influence the process of fiber formation occurring between the spinneret and the take-up unit.

The *fiber diameter* d, in millimeters, can be calculated from the titer with the aid of the volume density ϱ. For a fiber with a circular cross section:

$$d = 0.02 \times \sqrt{\frac{T}{\pi \cdot \varrho}}$$

where T is expressed in decitex and ϱ in grams per cubic centimeter.

2.1.2. Theory and Mechanism of Spinning

2.1.2.1. Spinnability of Fluids

Spinnability, i.e., the ability to form threads, is exhibited by many materials which differ widely in structure and composition; it is by no means

a unique property of macromolecules. Chain-like macromolecules are, however, a prerequisite for the production of useful fibers with good mechanical properties. According to Ziabicki [1], the maximum thread length attainable on application of tensile stress is a measure of spinnability. The maximum thread length L depends not only on the material, but also on the spinning conditions. For a given substance, L depends primarily on the product $v \cdot \eta$, where v is the pulling velocity in meters per second and η is the shear viscosity. As shown in Figure 1, L passes through a maximum at intermediate $v \cdot \eta$ values where it is affected to some extent by the ratio of surface tension to viscosity.

Figure 1. Maximum length L of a fluid thread as a function of the product of pulling velocity v and shear viscosity η. A thread was pulled by a rod from solutions containing the indicated concentrations of cellulose acetate in weight percent; intrinsic viscosity $[\eta] = 1.92$ dL/g in an 85 : 15 (vol : vol) acetone – water mixture [3]

A fluid, as-spun filament is thought to break by two mechanisms [4]. The first of these is *cohesive failure* in which fracture occurs when the tensile stress exceeds the tensile strength of the material at some point along the path of filament formation. Tensile strength depends on the energy of cohesion (critical elastic energy) of the material. Tensile stress can build up if the fluid, in contrast to ideally viscous Newtonian media, is able to store energy of deformation, i.e., if it is viscoelastic. The second failure mechanism is termed *capillary wave failure* and depends on the ratio of surface tension to viscosity. The larger the ratio, the more rapid is the increase in the amplitude of initially minute waves on the filament surface. After a certain distance, the capillary filament is divided into droplets and breaks (a fine stream of water also exhibits this type of behavior).

Depending on prevailing conditions, the filament will fail by the mechanism that predicts failure at the shorter filament length. By plotting theoretical curves for both models, a region of spinnability becomes apparent which coincides with that observed in practice (see Fig. 2).

Figure 2. Superposition of theoretical curves of capillary wave failure (— — —) and cohesive failure (. . . .).
The maximum length L of a fluid filament is plotted as a function of the product of the extrusion velocity v_0 and the shear viscosity η; d_0 = initial diameter; $\xi = \mathrm{d}\ln(v/v_0)/\mathrm{d}x$ = axial deformation gradient; σ_s = surface tension; K = energy of cohesion; τ = relaxation time, time for the stress (stored energy) created by a sudden deformation to decay to the (1/e)th part [4].
The arrows show the direction in which the theoretical curves shift when the indicated parameter increases

2.1.2.2. Flow Processes in Spinning

Internal and external flow processes occur during fiber spinning. The flow of the spinning mass toward the spinneret and its passage through the spinneret holes are termed *internal processes*. The *external processes* include the behavior of the jet of spun material on leaving the spinneret hole, as well as drawing and solidification of the fiber. The flow processes occurring inside and on leaving the spinneret are governed by the shear flow properties of the spinning mass under the prevailing extrusion conditions (i.e., shear viscosity η and shear rate $\dot{\gamma}$). Subsequent flow processes are characterized by drawing properties and conditions (extensional or elongational viscosity η_D and elongation rate $\dot{\varepsilon}$). These two types of flow are shown schematically in Figure 3.

Flow Properties of Fluids. In contrast to solids, liquids begin to flow continuously when

Figure 3. Schematic of flow processes in fiber spinning
A) Laminar shear flow shown as simple shear between horizontal layers and as tubular flow with telescopic shearing; B) Monoaxial, steady-state elongational flow
F = force; A = area; x = coordinate axis; r = radius; v = velocity

a force is applied. If the force is applied tangentially to a given plane, an equal and opposite force must act on the opposing interface, and shear flow occurs. Infinitely thin laminar layers are displaced in parallel and exhibit a velocity profile; the energy brought into play is converted to frictional heat. In tubular flow, the layers are concentric and the driving force is applied to the circular face. The opposing force is created by friction against the tube wall. The layers shown in Figure 3A must be imagined as being infinitely long in the direction of flow. In the steady-state, the fluid leaving the element under consideration is constantly replaced. The following terms are defined in laminar, linear shear flow:

Shear rate	$\dot{\gamma} = \mathrm{d}v\,(x)\,/\mathrm{d}x$ for a planar surface, or $dv\,(r)\,/\mathrm{d}r$ for a tube
Shear stress	$\tau = F/A$
Shear viscosity (also called Newtonian viscosity or dynamic viscosity)	$\eta = \tau/\dot{\gamma}$

where x = coordinate axis, v = velocity, r = tube radius, F = applied force, and A = area.

Thus, to achieve a given average flow rate, a force must be applied which is proportional to the shear viscosity of the material used.

In Newtonian fluids, η is constant over the entire range of shear rate (i.e., η is a material constant). However, polymer melts and polymer solutions used in fiber production generally exhibit a more complex behavior. They are pseodoplastic (η decreases as the shear rate increases, i.e., non-Newtonian) or viscoelastic (viscosity is time-dependent), and also display rubber-like elastic deformation. GLEISSLE discovered that all three phenomena can be attributed to the elastic behavior of polymers [5]. Thus, the steady-state viscosity function $\eta\,(\dot{\gamma})$ can be used to deduce the time-dependent behavior of a viscoelastic fluid under stress (mirror relations). At the molecular level, the high elasticity of polymers, in contrast to solids, cannot be explained by interatomic forces (with correspondingly low elongation). In macromolecular chains, the restoring force is instead produced by entropy effects which are based on the relatively unhindered rotation of the main single valence bonds and the nonextended bond angles. The most entropically favorable (i.e., most probable) conformation is that of a ball with randomly coiled chains [6]. In the absence of an external elongational force, the macromolecular polymer chains will adopt this conformation.

Elongational flow occurs when a force acts perpendicular to an area with a finite cross sec-

tion (see Fig. 3B). Because the volume of an incompressible fluid must remain constant, elongation is accompanied by a simultaneous transverse contraction. Hence during steady elongational flow, an infinitely small volume of fluid with an initial cross section A_0 accelerates in the direction of flow under the action of the elongating force. In the steady state, the outflow is continuously replaced by inflow through the area A_0. The following terms can be defined and are analogous to those already given for shear flow:

Elongation rate	$\dot{\varepsilon} = \mathrm{d}v(x)/\mathrm{d}x$
Tensile stress (also called elongational or normal stress)	$\sigma = F/A(x)$
Elongational viscosity (also called extensional or Trouton viscosity)	$\eta_\mathrm{D} = \sigma/\dot{\varepsilon}$

Figure 4. Steady-state shear and elongational viscosity as a function of the rate of deformation
Measurements were performed on branched polyethylene at 150 °C [7] (η = viscosity; η_D = elongational viscosity; η_0 = limiting viscosity at zero shear)

For an incompressible Newtonian material the following relation holds: $\eta_\mathrm{D} = 3\,\eta$ (analogous to the material parameters during the deformation of a solid). For non-Newtonian materials this relation is valid only at low rates of deformation (see Fig. 4); under these apparently Newtonian conditions, the steady-state viscosity does not change (i.e., $\eta = \eta_0$, where η_0 is the limiting viscosity at zero shear). As shown in Figure 4, further elongation is at first accompanied by consolidation, i.e., η_D increases. The shear viscosity η simultaneously decreases, however, because the shearing force increasingly orients the randomly coiled, ball-shaped molecules into elongated threads; consequently, the flow resistance drops.

Flow Processes in the Spinneret and Filament Formation. The most obvious evidence for the elastic behavior of polymers and their solutions during spinning is the fact that the extrudate leaving the spinneret has a larger diameter than the spinneret hole (see Fig. 5A). This effect is called die swell, onion formation, or the Barus effect. The ratio of the maximum diameter of the extrudate to the diameter of the spinneret, d_max: d_0, is called the die swell ratio or swelling factor.

Figure 5. Spinneret flow and die swell ∗
A) Deformation of a cylindrical fluid element during extrusion through a spinneret; B) Flow of fluids out of a tube
d_0 = capillary diameter; d_max = maximum diameter of the extrudate
∗ Reproduced with permission from [8].

There are two reasons for die swell:

1) The inflowing mass in front of the spinneret capillary is subjected to an elongating deformation in addition to shear. The resultant elastic stress partially relaxes during flow through the spinneret capillary, the residual elasticity increases with decreasing residence time (i.e., lower ratio of the capillary length l to the capillary diameter d_0). Once the mass has left the spinneret, its diameter is

not limited by the capillary walls; the residual elasticity recovers, and this leads to expansion. The $l:d_0$ ratio usually varies from 1 to 3. Values for d_0 range from 0.1 to 0.4 mm with residence times of 10^{-4} to 10^{-2} s; polymer relaxation times can be as high 1 s.

2) Even polymer melts or solutions which emerge from a long tube without an orifice exhibit an increase in diameter (Fig. 5B). As mentioned previously, this is because shear flow produces entropy – elastic molecular orientations, as a result of the radial velocity field; a persistent tensile stress is thus created which is a function of the shear velocity (dynamic orientation).

For non-Newtonian fluids, the sum of these two elastic deformations causes the emerging filament to contract. The contraction in length is proportional to the square of the simultaneous swelling (die swell) factor. Under normal conditions, the filament diameter expands to 1.1 – 2.5 times the capillary diameter. For a viscous Newtonian fluid, however, the diameter of the emerging strand is approximately 14 % smaller than that of the capillary (see Fig. 5B).

For a complete description of the deformation of non-Newtonian materials during shear flow (such as die swell), normal stresses occurring along the three major coordinates must also be considered [8]. In the limiting case of incompressible fluids, rheology is not affected by absolute hydrostatic pressure; only the differences between the normal stresses are important. These are defined as follows (see also Fig. 6):

$$N_1 = \tau_1 - \tau_2 \text{ (first normal stress difference)}$$

$$N_2 = \tau_2 - \tau_3 \text{ (second normal stress difference)}$$

where τ_1, τ_2, and τ_3 are the normal stresses acting on the areas perpendicular to the three space coordinates.

In the case of simple, linear shear, $N_2 = 0$ and $N_1 = \theta \cdot \dot{\gamma}^2$, where $\dot{\gamma}$ is the shear rate and θ is the normal stress coefficient for the steady state. The parameter N_1 has the same effect on a fluid stream as an externally applied tensile stress. The resultant phenomena are called normal stress effects or the Weissenberg effect.

The mirror relations derived by Gleissle [5] can be used to calculate θ directly from the viscosity function $\eta \cdot (\dot{\gamma})$. The parameter θ is the greater, the more the shear viscosity has been reduced by the shear rate $\dot{\gamma}$. The importance of normal stresses is illustrated by the fact that, for the polymers used in the manufacture of man-made fibers, N_1 is greater than τ, even at low shear rates $\dot{\gamma} =$ ca. $10^{-1} - 10^{-2}\,\mathrm{s}^{-1}$).

Figure 6. State of normal stress in a fluid element
p = hydrostatic pressure acting on all sides; τ_1, τ_2 and τ_3 = normal stresses acting on the areas perpendicular to the coordinates x_1, x_2, and x_3, respectively

Shear rates at the walls of spinneret capillaries are usually $10^2 - 10^5\,\mathrm{s}^{-1}$. If the ratio $N_1 : \tau$ becomes too large (i.e., if the shear rates are too high), melt fracture occurs. Melt fracture is a form of unstable flow that is produced by oscillating elastic deformations. This instability is not related to the Reynolds criterion for turbulence used in hydrodynamics. Melt fracture can be recognized by the fact that the filament emerging from the spinneret is not smooth: its diameter is irregular and varies more or less periodically

Figure 7. Velocity profile of an extruded, tapering filament
d_0 = capillary diameter; $d_{\max}$ = maximum filament diameter; $\dot{\gamma}$ = shear rate; $\dot{\varepsilon}$ = elongation rate; x = distance from the spinneret orifice

Figure 8. Schematic of the spinning process [12]

[9], [10]. GLEISSLE [11] discovered a universal critical value of the ratio $N_1 : \tau$ for different polymers, above which melt fracture occurs:

$$(N_1/\tau)_{\text{crit}} = 4.6 \pm 0.2$$

The spinneret hole diameter is the major factor affecting the shear rate and therefore the first normal stress difference N_1. The diameter must therefore have a suitable minimum value; its upper limit is determined by the fact that the spin-draw ratio and elongation rate must not be too great if excessive preorientation and cohesive failure are to be avoided.

Under steady-state conditions, the extruded filament exhibits the velocity profile shown in Figure 7. A parabola-shaped, shear flow profile develops in the spinneret capillary. After the material leaves the spinneret, the profile flattens out because frictional force is no longer exerted by the capillary walls and deceleration results simultaneously due to swelling. Once the maximum filament diameter is reached, normally within a distance of 1 – 3 mm, the tensile force begins to act on the fluid thread. The radial velocity over the whole cross section is constant; hence, the jet of spun fluid is accelerated and begins to taper. Under normal spinning conditions, the axial velocity gradient is ca. 10 – 70 s^{-1}, the largest deformation occurring within the first 20 – 30 cm. Spinnability is stabilized by the onset of coagulation or solidification and, at least in the initial region, by the increase in elongational viscosity shown in Figure 4.

The typical behavior of several fiber parameters during spinning is depicted schematically in Figure 8. Consolidation of the filaments, in the sense of solidification, is achieved by cooling (quenching) or coagulation in a spinning medium and is associated with an increase in the limiting viscosity at zero shear η_0. Since relaxation is slower in a viscous mass, the buildup of tension resulting from the elongating forces and increased viscosity is accompanied by an

increase in molecular orientation along the filament axis. This orientation can be measured by birefringence and remains in the as-spun filament after it has solidified at its glass transition temperature. The glass transition temperature corresponds to the softening point of the amorphous polymer regions; the melting point of a polymer, however, is defined as the melting point of its crystallites, above which the melt is thermoformable. Once the solidification point has been reached and deformation is complete, the stress continues to increase because of external friction between the thread and the spinning medium.

Figure 9. Balance of forces in a spun filament (direction of spinning is downward)
d = filament diameter; d_0 = capillary diameter; d_{max} = maximum filament diameter; x = distance from spinneret; v = filament velocity; θ_s = solidification temperature; subscripts S and L indicate solidification point and end of spinning path, respectively (see text for definition of forces)

Partially crystalline regions may be formed during spinning, depending on how rapidly the polymer tends to crystallize. In general, however, crystallization is difficult to predict because the interaction of polymer properties, spinning conditions, orientation, and crystallization are complicated.

During spinning, a filament is subject to the balance of physical forces shown in Figure 9. The first detailed investigation of the forces operating during spinning was carried out by Ziabicki [13]. At any given distance x from the spinneret, the retarding forces are balanced by the deformation forces:

$$F_{rheo}(x) = F_{ext} + F_{grav}(x) - F_{inert}(x) - F_{fric}(x) - F_{surf}(x)$$

where

F_{rheo} = rheological (viscous) force, tensile force
F_{ext} = external take-up force (constant along the entire threadline)
F_{grav} = force of gravity (weight of filament suspended from point x) – if the fiber is spun vertically upward F_{grav} is negative; if it is spun horizontally, F_{grav} is zero
F_{inert} = force of inertia (due to acceleration to v_L, the velocity at the end of the spinning path)
F_{fric} = frictional force between the surface of the filament and the spinning medium
F_{surf} = force due to surface tension (tends to minimize surface area of the filament by shrinkage)

At the solidification point ($x = x_s$) and thereafter, F_{inert} is zero; in addition, the surface and interfacial tension are often negligible. At the end of the spinning path ($x = x_L$), F_{grav} (in downward spinning) and F_{fric} also equal zero; at this point, the tensile force applied to the filament, F_{rheo}, is therefore equal to the external take-up force. Complicated mathematical procedures are, however, required to predict the course of filament formation (i.e., decrease in diameter) from the elongational viscosity and the calculated force components on the right-hand side of the above equation.

2.1.3. Melt Spinning

Melt spinning is the simplest spinning process. It is applied to polymers that can be melted and which do not decompose or change substantially

when maintained in the molten state for several minutes at a temperature up to 300 °C (e.g., polyesters, polyamides, polyolefins). The highly viscous melt is forced through a spinneret at a high pressure (ca. 10 – 20 MPa), therefore the spinneret plate has to be quite thick (ca. 10 mm). Figure 10 shows the geometry of a spinneret hole used in melt spinning.

Figure 10. Vertical section through a spinneret hole used for melt spinning
α = countersink angel; β = angle of transition; d_0 = capillary diameter (ca. 0.2 – 0.4 mm, permissible variation = ±0.002 mm); D = prechannel diameter; l = capillary length (ca. 2 d_0)

After leaving the spinneret, molten filaments are cooled (quenched) in air as a spinning medium; cooling is usually accelerated by blowing the air across the filaments. In special cases, a liquid is used as a spinning medium to accelerate cooling even further (see also production of monofilaments, Chap. 5). This is not to be confused with wet spinning, which is dealt with in Section 2.1.4.2.

The key characteristic of melt spinning is that the filaments are extruded from a melt and solidified by heat exchange with a spinning medium. Since no exchange of material occurs, under steady-state conditions the equation of continuity (the simplest form of material balance) applies at every distance x along the filament:

$$\varrho \cdot A(x) \cdot v(x) = G = \text{constant}$$

where

ϱ = polymer density
A = cross-sectional area of filament
v = filament velocity
G = polymer throughput per spinneret hole (e.g., grams per minute)

If the filament cross section is circular and $A = \pi d^2/4$
(d = filament diameter), it follows that

$$v(x) = \frac{4G}{\pi \varrho d(x)^2} \text{ or } d(x) = 2 \times \sqrt{\frac{G}{\pi \varrho v(x)}}$$

Hence, the decreasing diameter of the as-spun filament is a direct measure of the increasing speed during spin elongation. Because frictional forces are relatively low when spinning is performed in air, take-up speeds of 8 – 25 m/s are obtained in classical melt spinning; speeds up to 100 m/s or more are possible in high-speed spinning [14].

Mathematical Models. Melt spinning is the spinning process most easily described by theoretical models and mathematics. Terms have been derived for the force and heat balance required to quantitatively describe filament formation during melt spinning [13], [15]. The heat balance is necessary to calculate the temperature-dependent elongational viscosity. Hamana [16] derived a coupled system of three first-order differential equations containing the filament variables velocity $v(x)$, tensile force $F_{\text{rheo}}(x)$, and temperature $\theta(x)$. The equations and both the initial and boundary conditions also take into consideration the physical properties of the polymer and air, as well as the spinning parameters (diameter of the spinneret hole, extrusion temperature, throughput per hole, take-up speed, and velocity of blown air). The mathematical solution of this system of equations is difficult because it requires numerical integration and knowledge of the initial value of the filament tensile force at the spinneret, F_0. The parameter F_0 is defined indirectly by the boundary condition that the filament speed must equal the take-up velocity when the filament reaches the take-up unit or is at its glass transition temperature. Hence, the solution requires several iterative integrations in which an estimated initial

value of F_0 is fitted until it meets the boundary condition.

Figure 11. Temperature variation along a bundle of filaments during melt spinning of poly(ethylene terephthalate) (PETP) [17]
Spinning path, ca. 1 m long; 70 °C isotherm = solidification curve at the glass transition temperature (T_g)

Computer Simulation. Hamana [16] was the first to write a computer program for simulating the melt spinning process. His measurements on the variation of temperature and diameter of poly(ethylene terephthalate) PETP and nylon 6 filaments confirmed his theoretical calculations. Poly(ethylene terephthalate) has a high glass transition temperature and does not develop any significant crystallinity during spinning up to medium speed. The birefringence, determined as a measure of molecular orientation, is proportional to the tensile stress calculated by the program. Furthermore, the birefringence of the quenched, as-spun filament corresponds to the tensile stress at the glass transition temperature. Mathematical simulation can thus be used to predict the properties of as-spun PETP filaments as a function of spinning conditions. The effect of spinning parameters on filament formation can be simulated easily, but this does not make spinning experiments superfluous.

Figure 12. Change in the cross section of nylon filaments spun from a spinneret with star-shaped holes [18].
Spinning length indicates distance between spinneret and liquid cooling bath

The program used by Hamana [16] has the drawback that it can only be used to simulate the formation of individual, isolated filaments under defined quenching conditions. In practice, fibers are spun in bundles which contain up to 3000 individual filaments, and quenching conditions varying considerably from filament to filament. Since air is blown from one side, cooling conditions can be very poor for filaments furthest from the air source for two reasons: (1) air reaching the rear filaments is already preheated and (2) the velocity of the transverse stream of air decreases because the front filaments entrain part of the blown air in their aerodynamic boundary layer [1]. Therefore, the program for individual filaments has been extended to include the heat and mass balance of air so that calculations

Figure 13. Tenacity versus take-up speed for PETP filaments of two different intrinsic viscosities [20], 1 cN/dtex $\triangleq$ 0.8839 g/den

Figure 14. Birefringence versus take-up speed for PETP filaments of two different intrinsic viscosities [20]

can be applied to the entire filament bundle. Figure 11 shows the isotherms obtained from such a simulation. The cooling path in the first row of filaments is quite short and corresponds to that obtained for individual filaments. However, filaments in the fifth and subsequent rows take about twice as long to solidify. In practice, this can lead to undesirable sticking when the filaments come into contact with one another. Fiber quality data and the filament-yarn bundle simulation program have been used to show how air blowing and quenching can be improved and standardized without having to reduce the number of filaments [17].

Filament Shape. Noncircular spinneret holes may be used to shape the filament profile and thus modify the properties of the product (e.g., luster, touch, coloration). The cross section of the spun filaments generally differs from that of the spinneret holes because surface tension tends to minimize the surface area of the filament. For any given length, a minimal surface area is achieved when the cross section is a solid circle. This change, however, does not occur instantly because it is retarded by viscosity. An example of the change in cross section along the spinning path is illustrated in Figure 12.

A well-developed profile is obtained by spinning at a low temperature, with rapid quenching; the viscosity then increases rapidly and the profile is "frozen" when the glass transition temperature is reached. The spinning temperature must not be too close to the polymer melting point because the swelling factor increases significantly just above the melting point, which makes the emerging filament rounder. Cooling conditions are most difficult to prescribe for hollow fibers spun from spinnerets that usually consist of a ring slit that is divided into one or more segments by fillets (see Fig. 67); individual segments must then flow together before solidification occurs. The external pressure is higher than that inside the hollow filament cavity and thus reduces the size of the cavity. As a result of this pressure difference, the air which later fills the hollow filament flows into or is sucked into the filament immediately below the spinneret; it enters at the fillets between the circular segments, before the filament closes up. Expensive spinneret designs have been patented in which this problem is overcome by spinning the hollow filament from a closed ring and blowing an inert gas into the center of the hollow internal cavity [19].

Filament Formation in Melt-Spinning Processes. In the 1970s a new fiber manufacturing process was developed that combined drawing and texturing. With this new process, undrawn, partially oriented yarn (POY) is still produced today. In the case of poly(ethylene terephthalate), PETP, the spinning speeds of this

process is between 2700 and 3500 m/min, depending on the desired product. However, higher spinning speeds are disadvantageous for the producer because of the increase in orientation and crystallinity, which deteriorate the required properties of this pre-yarn. At spinning speeds above 3500 m/min the textile physical properties of the textured yarn are negatively influenced. Especially the draw ratio in the texturing process is much lower than that of conventional POY, so that the productivity would be reduced. Because the draw ratio is lower and the final titer (fiber diameter) is fixed, the POY titer must also be reduced. Hence, if a conventional PETP is used, typical limits exist which are attributable to the inherent properties of the spin polymer or the corresponding polymer physics.

Which factors influence the fiber formation process? For two different intrinsic viscosities (IVs), Figures 13, 14, and 15 show the tenacity, crystallinity, and birefringence as a function of spinning speed [20]. For an intrinsic viscosity of 0.95 dL/g, which corresponds to high molecular mass PETP for the production of tire cord, molecular orientation (birefringence), crystallinity, and tenacity already increase at relatively low spinning speeds.

Figure 15. Crystallinity versus take-up speed for PETP filaments of two different intrinsic viscosities [20]

For both IVs a maximum exists in all three diagrams, but to a first approximation the curves for the higher molecular mass, which corresponds to higher intrinsic viscosity, are shifted to lower spinning speeds, and the maximum heights of the curves are different. For a higher intrinsic viscosity (0.95 dL/g) the onset of the strong increase in molecular orientation starts at lower velocities, but the maximum attained by the low-viscosity PETP is higher (Figs. 13, 14, 15). Therefore, by varying the intrinsic viscosity, it is possible to shift the molecular orientation at a given spinning speed to lower or higher values. But this adjustment is limited. Not every molecular mass is suitable for all kinds of end product. However, polymer modifications can also be used to influence the POY textile physical properties (see page 16).

Figure 16. Fine-structure model for a spinning speed of 10 000 m/min [24]

Morphology of the As-Spun Fiber. Figure 16 shows the morphology of a semicrystalline PETP fiber. Between the crystallites, which are always more or less highly oriented, are the noncrystalline regions, which begin to orient themselves at a certain spinning stress. When a critical molecular orientation is attained, the intermolecular forces are so high that crystallites are spontaneously formed (Fig. 17) [21]. In high-speed spinning, the structure-forming process is so fast that inter- and intrafibrillar voids are generated. This can be detected by the positron-annihilation method, whereby the lifetime of the positron is used to detect voids in the polyester [22]. Positrons and electrons can form a positronium atom, the annihilation

characteristic of which can be used to measure the microvoids in the polyester [23].

Figure 17. Model for PETP crystal growth under high tensile stress [21]
F and $F*$ are forces ($F* > F$)

Because of the different fiber morphology that results from high-speed spinning as compared to conventional low-speed processes, dye pickup is drastically improved.

The molecular chain alignment at which the fiber is still noncrystalline is called the amorphous orientation or oriented meso phase. The meso phase is intermediate between a totally coiled amorphous polymer chain arrangement and a highly ordered structure which launches the crystallization process above a critical degree of orientation. Figure 18 shows the development of the molecular orientation, beginning with the free-fall yarn directly under the spinneret to the oriented meso phase, the necklike deformation, and ending with the semicrystalline end state of this spin yarn [25], [26].

The amorphous orientation can be measured by different methods. Beside the investigation by the birefringence method [27], the amorphous orientation of PETP can be measured directly by detecting the natural intrinsic fluorescence of its benzene rings [28]. Crystallite sizes, intrafibrillar distances, and crystallite orientation are detectable by X-ray investigations [29].

Radial Distribution of Molecular Orientation. The higher the spinning velocity at a given fiber diameter, the more inhomogeneous is the radial distribution of the molecular orientation in the as-spun fiber [30], [31]. A synonym for this morphology is skin – core structure.

This characteristic morphology can be clearly observed in yarns which were spun at very high velocities, e.g., speeds higher than 7000 m/min. This molecular structure can be measured by the birefringence method as a function of the fiber diameter (Fig. 19) [32–35]).

Figure 18. Changes in fiber structure during high-speed spinning [25], [26]

Figure 19. Radial distribution of birefringence at different take-up speeds (Take-up velocity in km/min) [32]

Figure 20 illustrates the radial distribution of the polymer (fiber) velocity gradient, the temperature in the filament, the corresponding spinning stress, and the resulting distribution of the molecular orientation (birefringence) [36].

At extreme spinning velocities with very fast cooling of the filament, the orientation process can only take place at the outer parts of the fiber [32], [24]. So at ultrahigh spinning speeds, e.g., 10 000 m/min, the spinning stress is concentrated in the boundary layer. However, a certain minimum spinning stress and enough orientation time are required for development of high molecular alignment and crystallinity. Hence, the molecules in the skin part of the fiber, which are oriented first, are frozen before the spinning stress can propagate through the whole thread. The result is a very inhomogeneous radial orientation distribution. The skin part is much more highly oriented than the molecules in the middle of the fiber. This characteristic form is generally called skin/core structure.

Further investigations of the development of the skin/core structure in fiber spinning can be found in [37–39], [40].

Polymer Modification. Polymer additives can be favorably used to influence the development of the fiber morphology. Chemical modification is performed by several producers. But these chemical modifiers have limits because the high concentrations which would have to be used to strongly influence the fiber properties deteriorate the textile physical properties of the products. So mostly these are not suitable for the conversion to end products.

Beside chemical polymer modifications [41], also polymeric additives are used, for example, to influence the orientation of the molecular chains in the fiber. The resulting polymer blends can be classified as two-phase, one-phase, or intermediate systems. Where phase separation occurs, the components are incompatible.

A polymer blend consisting of polystyrene/polypropylene and polystyrene/high-density polyethylene yields a decrease in melt viscosity [42], [43], and a decrease in melt viscosity was observed for polyethyleneterephthalate/PA66 blends [44]. Interesting fiber properties were obtained by adding a liquid-crystalline copolymer to polyethyleneterephthalate as a modifier. At a given take up velocity the molecular orientation could be drastically reduced so that the elongation at break (extension) was substantially increased (Fig. 21) [45], [46].

The addition of liquid-crystalline polymers is very effective with regard to the elongation increase, but the advantages in production cost limited because of the high price of such additives.

The elongation increase on adding a further polymer can be attained also in the case of nylon and other matrix polymers. Poly(methyl methacrylate) was also effective, but concentrations of more than 2 % are required to give a sufficient increase in elongation increase at higher velocities, for example, at spinning speeds of 5000 m/min [46]. Additionally yarn breaks were observed at high velocities.

An additive consisting of 50 – 90 % imidized polymethacrylic acid alkyl ester [48] can be used concentrations of less than 1 wt % for the above applications. The additives are mostly used for the production of yarns which can be directly used (fully drawn yarn). The advantage of this kind of modifier is its high effectiveness; the disadvantage is the high price of such copolymers. A further copolymeric additive consisting of two of the monomers A, B, and C, where A is polystyrene or methyl-substituted polystyrene; B is imidized maleic anhydride; and C is maleic anhydride or maleic acid is described in [49].

For POY processes which run at high speeds of, for example, 5000 m/min Stibal [50] describes an investment cost advantage of 25 % and the corresponding production cost saving for

Figure 20. Radial distribution of take-up speed, viscosity, spinning stress, and molecular orientation [36]

Figure 21. Fiber elongation with different modifiers (Santicizer, X7G, Cloth, Central) [45], [46]

a melt modification process in continous polymerisation plants. The fiber forming process is in general an elongation process. So when incompatible polymeric additives are added to a polymer melt, additional shear forces occur between the matrix and the additive [45], and rotational components are developed during the fiber forming process (Fig 22), [51]. At the same time the morphology is frozen by fast cooling, so that the orientation of the resulting fiber is reduced. The orientation decrease can be measured by an increased elongation at break and/or by a reduction in birefringence (Figs. 23 and 24), [52].

2.1.4. Solution Spinning

Polymers that do not meet the requirements for melt spinning may be spun if they can be dissolved in a suitable solvent. The polymer swells when dissolved and may form a completely homogeneous solution, depending on prevailing bonding forces and interactions. Polymers prepared by solution polymerization (e.g., polyacrylonitrile) can be spun directly without intermediate processing. Much lower spinning pressures (ca. 0.5 – 4 MPa) are used than in melt spinning because the dissolved, diluted polymer flows more freely than a polymer melt. Polymers with a very high molecular mass (generally up to a weight-average molecular mass $\bar{M}_w$ of 250 000) can also be spun. This is not possible in melt spinning because the limiting viscosity at zero shear η_0, and thus the spinning pressure, increase in proportion to $\bar{M}_w^{3.4}$. In solution spinning, the effect of molecular mass on viscosity can be compensated for by appropriate dilution [1], [53]. However, the concentration should not be too low since this reduces polymer throughput and increases the cost of solvent recovery.

2.1.4.1. Dry Spinning

In dry spinning, the polymer solution is spun into a hot gas whose temperature is higher than the normal boiling point of the solvent. The solvent thus evaporates, most of the heat of evaporation being supplied by the drying gas which also removes solvent vapor. Evaporation of the solvent along the spinning path is determined mainly by its rate of diffusion through the filament, which

Figure 22. Structure-formation process related to the reduction of molecular orientation resulting from a polymer additive [51]

Figure 23. Fiber elongation versus spinning speed for physically modified (HP5000 PETP) and unmodified PETP polymer [52]

Figure 24. Birefringence versus spinning speed for physically modified (HP5000 PETP) and unmodified PETP polymer [52]

decreases as solidification progresses. Solidification occurs as a result of the decrease in solvent concentration and the associated increase in viscosity; the filament passes through a gel form into the solid phase. Since the heat supplied to the filament by the drying gas is largely dissipated by solvent evaporation, the temperature of the filament does not change significantly. The temperature increases only toward the end of the spinning path. Solidification by means of material transport (i.e., diffusion of solvent from the interior of the filament to the surface and subsequent evaporation) leads to pronounced radial inhomogeneities, particularly in spinning solutions with low polymer concentrations. Since solidification proceeds more rapidly at the surface of the filament than inside, a typical sheath–core structure is formed. Diffusion of the solvent which remains in the interior is thus hindered by the already solidifying skin. If evaporation from the surface is very rapid, the skin becomes so solid that its circumference remains practically constant. Further diffusion of solvent from the core results in a loss of mass from the interior, with formation of cavities and negative pressure; the skin then collapses and folds inward. The resulting filaments display cross sections that have the appearance of wrinkled lobes, almost like a peanut.

In dry spinning, the filament always has a residual solvent content of 5–25 wt %, which exerts a plasticizing action. This is desirable because it facilitates subsequent drawing of the filament; therefore the residual solvent is removed later in the process.

The spin-draw ratio based on the extrusion rate of the spinning solution ranges from 1 to 10 and is thus substantially lower than that found in melt spinning which may be as high as several hundred. The ratio is lowered by a factor of $1/c_p$ due to dilution alone (c_p is the polymer concentration).

Figure 25. A triangular diagram representing a ternary mixture.
Points A, B, and C represent the pure components; point M represents a mixture with composition $x_A + x_B + x_C$; the dashed lines pass through M and are parallel to the sides of the triangle

Although general physical laws and models of material transport are applicable to dry spinning, a mathematical description is even more difficult to derive than for melt spinning [1], [54]. A simple model for the upper part of the filament (where diffusion is not limiting) is based on the assumption that the ratio of the material transfer coefficient to the heat transfer coefficient is constant. For an overview of the dependence of fiber properties on dry-spinning parameters, see [55].

2.1.4.2. Wet Spinning

Wet spinning is used if the polymer is dissolved in a nonvolatile solvent or if the polymer dissolves only after chemical transformation (which necessitates a subsequent reverse reaction). In wet spinning, the polymer solution is spun into a liquid coagulating bath. Heat exchange with the spinning medium is not responsible for solidification of the filament. Instead, solidification occurs as a result of coagulation caused by phase separation. Phase separation is induced by a component of the spin bath which is incompatible with the polymer (i.e., a nonsolvent). The polymer, solvent, and nonsolvent constitute a ternary system, and processes occurring during wet spinning can best be explained by using a triangular diagram as shown in Figure 25. The pure components A, B, and C are represented by the corners of an equilateral triangle. Point M then represents a mixture with the composition $x_A + x_B + x_C = 100\,\%$. If M lies on an edge of the triangle, the mixture is binary.

Figure 26. Phase diagram of a ternary system during wet spinning
Points: P = polymer; S = solvent; N = nonsolvent; SF = spinning solution; PB′ = inflow into coagulating bath; M = composition of mixture (on mixture line according to the law of leverage); G = gel-like filament after phase separation (in thermodynamic equilibrium); PB″ = outflow from coagulating bath (located opposite G on the binodal curve)
a) Binodal curve (limit of miscibility gap); b) Mixture line; c) Line of phase equilibrium (passing through M); d) Two-phase region (miscibility gap, shaded); e) Path of change in composition of the spun filament in the coagulating bath (diffusion-controlled)

Figure 27. Filament formation during wet spinning [2]
The stippled area indicates coagulation

The situation in the coagulating bath is depicted in the form of a triangular phase diagram in Figure 26. The most important feature is a rather broad (shaded) immiscible region under the so-called binodal curve. Any mixture which, based on its average theoretical composition, lies in this region separates into two immiscible, liquid phases. The composition of these two phases is given by the points at which the equilibrium line passing through M intersects the binodal curve. (Any two opposing points on the binodal curve are connected by such a line.)

The nonsolvent N (frequently water) must be chosen so that it is miscible with the solvent S in all proportions. When the spinning solution SF enters the coagulating bath with an initial composition PB′, the total mixture can be represented by the point M; the position of M on the line connecting SF and PB′ is such that the ratio of the distance SF–M to the distance PB′–M is the same as the ratio of the amount of PB′ to the amount of SF (law of leverage). By using point M as an aid in graphic construction, points PB″ (final composition of the coagulating bath) and G are obtained which correspond to thermodynamic equilibrium. Point G represents the final state of a swollen gel fiber; its surface corresponds to the interfacial boundary with the spin bath. The route by which G is attained, if at all, primarily affects the structure of the gel

Figure 28. Representative stress – strain curves of spun filaments

fiber being formed, it depends on the kinetics of solidification and on the residence time.

Figure 29. Draw point (bottleneck) and molecular orientation obtained during cold drawing

Two types of material transport occur during wet spinning, their rates are determined by diffusion constants. First, a flow of solvent S∗ occurs from the spinning jet into the spin bath. Second, a stream of nonsolvent N∗ diffuses into the spinning jet. The ratio S∗ : N∗ determines the change in composition of the original spinning solution SF [1]. If, for example, S∗ : N∗ = 1, the polymer concentration in the spinning jet does not change, i.e., a change in composition would proceed along a straight line starting at SF and run parallel to the side S – N of the triangle. Figure 26 shows a general route (e) which corresponds to S∗ : N∗ > 1. Phase separation begins at the point of intersection with the binodal curve; the filament coagulates and becomes gel-like. Its composition continues to change along the binodal curve in the direction of G, and the concentration of P increases.

As in dry spinning, well-developed sheath – core structures and cavities are also formed in wet spinning due to radial diffusion. In wet-spun polyacrylonitrile fibers, for example, this leads to filaments with kidney-shaped sections. Figure 27 represents the formation of a wet-spun filament. The composition of the spinning solution within the diffusion boundary has not yet changed. The coagulation boundary indicates the position of the binodal line. The spinneret holes have a characteristic shape and are about 0.1 mm in diameter. The thickness of the spinneret is only a few tenths of a millimeter.

In wet spinning, the spin-draw ratio is usually less than 3, and occasionally even less than 1. Spin elongation still occurs, however, due to the increased concentration of polymer in the spinning jet. High frictional forces in the fluid limit the spinning speed to about 0.8 m/s, which can be compensated for by a large number of spinneret holes. A survey of common solvents and coagulants used in wet spinning is given in [2].

A mathematical formulation for wet spinning is even more difficult than for dry spinning. White and Hancock [56] were the first to carry out precise analysis and model calculations.

2.2. Drawing

2.2.1. Elongation Properties of As-Spun Yarns

As-spun polymer filaments normally exhibit a low degree of molecular preorientation and crystallization; they can therefore still undergo considerable elongation in the cold state which may be as high as five times their initial length. Depending on the properties of the material and the temperature used for testing, elongation or draw-

ing produces one of the characteristic stress–strain curves shown in Figure 28.

If the glass transition temperature far exceeds the temperature of testing or if the filament is already crystalline, the tensile force (stress) increases rapidly but the filament breaks at low elongation (strain) (Fig. 28A). Conversely, the filament can exhibit a high plastic elongation with a slow increase in force if the testing temperature far exceeds the glass transition temperature (Fig. 28C). Figure 28B represents an intermediate stress–strain curve, where the testing temperature is close to the glass transition temperature and which is typical of *cold drawing*; this term was coined in the early days of synthetic fiber development to signify that drawing occurs far below the melting point. Cold drawing proceeds as follows: in the initial stage of low elongation, deformation is elastic and reversible, i.e., the molecules retain their mutual points of cohesion. At a certain critical stress $\sigma*$ (elongation $= \varepsilon_1$), the yield point is reached where the tensile force passes through a maximum. A constriction (bottleneck) then begins to form at a random point along the drawn filament. As elongation proceeds, this constriction wanders along the filament in both directions at constant yield force, resulting in the formation of a draw shoulder (telescope effect). In this region, drawing is heterogeneous. At an elongation ε_2, the draw shoulder occupies the whole length of the filament. Since a criterion of mathematical instability is met [1], filament regions of varying diameter will always exist between elongation values ε_1 and ε_2. The constricted region exhibits a reduced diameter, corresponding to a local elongation ε_2; the remaining sites are still not drawn, however, because they lie in the elastic region below the yield point. These undrawn sites disappear only when the filament is elongated to ε_2. The remarkable drawing factor $1 + \varepsilon_2$ is called the natural draw ratio and equals the ratio of the fineness of the undrawn regions to that of the constricted regions. Once ε_2 is exceeded, deformation again becomes homogeneous with increasing force (up to the break point). If the material has a higher preorientation, ε_2 is lower and the yield force is higher.

2.2.2. Mechanism of Cold Drawing

Cold drawing can be explained at a molecular level (see Fig. 29). In the undrawn filament the molecular chains are largely disordered and coiled but are immobile just below the softening point. Since the filament is extended beyond the region of reversible elongation, the irreversible part of the mechanical work of extension is converted to heat [1], which is concentrated in the zone of flow where deformation takes place. This local heating can lead to melting if the rate of elongation is too high; it provides the molecules with the mobility required for rearrangement and sliding during extension. Once the flow process has begun, the stress–strain curve in the zone of flow begins to change due to heating, so that a maximum loading at the stationary point of draw no longer has to be overcome.

The heat liberated during extension consists of two parts: (1) internal frictional heat and (2) heat produced by thermodynamic changes resulting from orientation of the molecules under stress. The thermodynamic changes can be explained as follows. Extension results in parallelization of the chain segments and a decrease in entropy. Neighboring molecules can nevertheless still interact with one another because of their temporary mobility. They thus assume a more energetically favorable crystal structure in which atoms of parallel molecular chains occupy the lattice points of a highly ordered, compact crystal lattice. The associated release of enthalpy thus results in an overall more favorable thermodynamic state than that of the frozen, amorphous, as-spun filament. Since the filament cools or coagulates during spinning, it does not have enough time to assume the most stable thermodynamic state permitted by the temperature of the surroundings, i.e., that of unordered crystallites, in which small crystals, also called micelles, are embedded in an amorphous matrix. A partially crystalline, as-spun filament would, however, have a lower residual drawability because the crystallites stabilize its morphological structure. Only those crystallites whose molecules are aligned at right angles to the fiber axis can be broken up and rearranged during drawing [57]. The polymer macromolecules are too long to be present in crystallites in extended form; they are usually folded several times and

arranged in lamellar planes which are perpendicular to the molecular axes (i.e., at right angles to the filament axis in the oriented state). Some molecules are anchored in two or more lamellae and are called tie molecules. They thus connect different crystalline regions in the longitudinal direction of the filament, which are separated by amorphous regions. Apart from the tie molecules, the amorphous regions contain only free chain ends and loosely folded loops. Together with chain loops, the tie molecules thus provide for force transfer within such microfibrils [58].

2.2.3. The Drawing Process

If filaments (e.g., PETP) with a uniform diameter are to be obtained by a continuous cold-drawing process, a draw ratio greater than the natural draw ratio must be used. This is accomplished with two sets of rollers running at different peripheral speeds; the ratio of these two speeds is the machine draw ratio. The number of yarn loops on each roll must be sufficient to prevent slippage according to the formula for rope friction, taking into account the drawing tension. Since a small proportion of the drawing deformation is elastic, the effective draw is slightly less than the machine draw ratio. When a draw point (bottleneck) appears in cold drawing, it must be stabilized locally within the field of drawing by frictional or thermal measures to maintain steady-state drawing [this is not necessary for plastic drawing (see Fig. 28C) at an approximately uniform rate of elongation].

The dynamics of drawing can be simulated mathematically [1]. As in melt spinning, the equation of continuity applies, but simulation is more difficult because of thermal and viscoelastic peculiarities. The drawing process can, however, be investigated on a laboratory scale by carrying out creep experiments in which the time-dependent change in length is measured under constant tensile force [59], [60]. The length of the drawing field (i.e., the distance between the sets of rollers) required at a given feed velocity can be calculated from these experiments. Various approaches can be used to reduce the drawing force and/or improve drawability; they all have the same objective – to soften the as-spun material by lowering its glass transition temperature T_g (with plasticizers, swelling agents, oligomers, or residual solvent) or by increasing the drawing temperature. Softening also leads to disappearance of the telescope effect. For example, PETP ($T_g = 70\,°C$) no longer forms a neck when drawn at 75 °C. If it is drawn in water, the plasticizing action of water begins to dominate at 50 °C, so that the drawing tension approaches zero above 90 °C [61]. Water is a good conductor of heat and thus prevents overheating of the flow zone which would otherwise increase the drawing force. When drawing takes place above the glass transition temperature, however, the relaxation time of the molecules diminishes rapidly, which means that stresses decay quickly, especially during slow drawing, and the original internal orientation is then reestablished. Thus only part of the filament extension has an orienting effect; the remainder produces flow. This fact can be exploited in extreme cases to produce superfine filaments. The as-spun filaments are first drawn without orientation in a hot-water bath or some other swelling agent (just below 100 °C in the case of PETP); orientation is then increased in a subsequent draw. This method permits very high elongations, which may be as much as 20 times the original length [62].

Figure 30. Stress – strain curves of poly(ethylene terephthalate) (PETP) filaments drawn at different draw ratios [12] Stress shown in the curves (σ_0) is based on the initial fineness; open circles indicate σ, the effective tenacity at break based on the actual fineness

2.2.4. Draw Ratio and Tensile Strength

Any material being spun can be subjected to varying degrees of draw. The draw ratio selected depends on the textile properties desired and the existing preorientation. As illustrated in Figure 30, the higher the draw ratio, the greater is the tenacity at break. At a higher draw ratio, the modulus of elasticity and the crystallinity increase, whereas the elongation at break is reduced.

The tenacity at break is equal to the force applied at break divided by the fineness. Since the actual fineness of the fiber at break is lower than its original fineness, the effective tenacity at break based on the actual fineness (σ) will be higher than the tenacity based on the initial fineness (σ_0). The two tenacities are related as follows:

$$\sigma = \sigma_0 (1+\varepsilon)$$

where ε is the elongation and is equal to $\Delta l/l_0$, Δl being the increase in fiber length and l_0 the initial length. In the case of low draw ratios close to the natural draw ratio, the effective tenacity is almost constant (see Fig. 30). A high draw ratio is required to obtain a large increase in tenacity.

The maximum fiber strength is obtained when the macromolecules are largely straightened out during drawing and are aligned along the longitudinal axis of the filaments so that they can crystallize. Since a molecular chain which is embedded and laterally anchored in the crystal lattice almost totally resists being pulled away along its axis, any subsequent tensile loading will put the greatest stress on the tie molecules which bridge the amorphous regions (cf. Section 2.2.2). If the load per tie molecule becomes too great, the filament breaks due to the rupture of the main bonds (C – C) of these force-transmitting chain segments. Because only a small fraction of the molecular chains (shown in the cross section of the drawn part of the filament in Fig. 29) act as force transmitters, the resultant strength is a fraction of that which is theoretically possible. Appropriate processing and use of a higher draw ratio increase the number of tie molecules and thus the tenacity at break up to a certain point by improving molecular uncoiling and alignment and preventing chain refolding. Two-step drawing may be important in this context [63]. The upper limit of drawing is reached when the tie molecules are fully extended. When the filament leaves the drawing zone, the chains in the amorphous regions recoil to some extent.

As explained previously, the value of the draw ratio used depends on the preorientation of the as-spun material which, in melt spinning, is largely governed by the take-up speed. Figure 31 illustrates the decrease in residual draw ratio with increasing take-up (spinning) speed, corresponding to a higher spinning orientation. However, this decrease is less pronounced than the concomitant increase in spinning speed. As a result, the spinneret throughput, and thus the productivity of a given spinning position, increase with increasing spinning speed, provided that the final fineness remains constant. (Only for polyamide does no advantage result from increasing the spinning speed in the range from 33 – 50 m/s.)

Figure 31. Total spinneret throughput and residual draw ratio as a function of winding (spinning) speed in melt spinning [64]
PA = polyamide; PES = polyester [poly(ethylene terephthalate)] ; —- Throughput; – – – – Residual draw ratio
Final yarn fineness = 167 dtex; Elongation at break = 25 %

High-speed spinning has become an important processing variant of melt spinning because only a low postdraw is then required, which is usually integrated into one of the other processing steps. High-speed spinning also reduces shrinkage due to formation of oriented crystallites [65].

2.2.5. Ultrahigh-Strength Synthetic Yarns

Maximum fiber strength would be obtained if very long (theoretically, infinitely long), completely extended polymer chains were to form an ideal, flawless crystal because they would then be in their most compact form and all be able to transfer force. In such a fiber, the macroscopic modulus of elasticity would correspond to the modulus of individual molecular chains (i.e., the strength of the C – C bonds). Theoretical tenacities of various polymers have been calculated [66]. Polyethylene is theoretically the most suitable polymer for obtaining fibers with very high strength because its chains have the smallest cross-sectional area. High-performance fibers with a very high molecular mass ($\bar{M}_w > 10^6$ g/mol) have been obtained from polyethylene by wet spinning (cf. Section 3.2.2.) [67]. The fibers have a tenacity of 3.5 GPa (35 cN/dtex), which far exceeds that of steel, but this still corresponds to only about 10 % of the maximum theoretical value. Ingenious drawing processes have been developed in an attempt to approach maximum theoretical values more closely [68], [69]. Very high tenacities have been achieved with liquid-crystalline, anisotropic polymer melts although their theoretical strength is distinctly lower than that of polyethylene.

When different materials are being compared, conversion of the textile tenacity σ in centinewtons per decitex to the tenacity σ_T in gigapascals (1 GPA = 10^9 N/m^2) may be useful:

$$\sigma_T = 0.1 \cdot \varrho \cdot \sigma$$

where ϱ is the fiber density (in g/cm^3). The term σ_T is commonly used for construction and reinforcement applications.

2.3. Crimping

2.3.1. General Description

Natural fibers, unlike synthetic fibers, have a so-called texture, which means that they are not straight but are crimped in three dimensions along their axes. This basic geometric property has shaped the design of fiber-processing machinery and largely determines the characteristics of yarns and fabric made from fibers.

The process used to impart a suitable texture to synthetic fibers which are processed into staple fiber or filament yarn is thus an important part of fiber manufacture.

The term texturing means the production of a permanent crimp in an initially straight fiber or filament yarn. Crimping is the result of local changes in the intermolecular interactions occurring in the polymers from which the fiber is made. The crimp is maintained to a greater or lesser degree during deformation or is stored as a type of memory [55], [70].

Crimp Rating. Many proposals have been made for rating crimp [71–74]; these include optical, mechanical [75], and thermomechanical [76] methods like those prescribed in DIN 53 840. Some important parameters for stuffer box crimped fiber are illustrated in Figure 32, others are:

$$\mathrm{KK} = (l_g - l_z)/l_g = \text{crimp contraction}$$
$$\mathrm{KG} = l_g/l_z = \text{crimp degree}$$
$$\mathrm{KB} = (l_g - l_b)/(l_g - l_z) = \text{crimp stability}$$

where

l_g = length of elongated (noncrimped) fiber
l_z = length of crimped fiber
l_b = length of crimped fiber after stress application

Figure 32. Structure of a crimped fiber (stuffer box)
α = buckling angle; l = buckling length; s = length of double arc

2.3.2. Crimping Processes

Various types of crimp and crimp stabilities can be obtained depending on the crimping process. Three main types are used: spontaneous, deformation, and bicomponent crimping.

Figure 33. A) Bicomponent spinneret for side-by-side (left) and sheath – core (right) filaments; B) Transverse and longitudinal sections through a side-by-side (upper) and sheath – core (lower) filament

Figure 34. A) Crimper with weighted swivel flap; B) Crimper with adjustable stuffer box
a) Incoming tow; b) Crimping rollers; c) Plug of material; d) Stuffer box; e) Crimped tow; f) Pressure applied to stuffer box

2.3.2.1. Spontaneous Crimping

Spontaneous crimping is caused by the anisotropy of various fiber properties such as density, molecular orientation, or crystallinity both in its cross-sectional plane and along its axis. Anisotropy can be obtained or reinforced by applying appropriate measures during spinning and drawing. In melt spinning, for example, the filament can be cooled on one side just below the spinneret by pulling it past a cooled body [77]. Alternatively, a swelling agent may be applied unilaterally in the spinning and/or drawing region. The resulting anisotropy causes differential stresses to be "frozen" into the filament which, when liberated (e.g., in hot water without tension), produce limited differences in shrinkage and, thus, irregular crimping of the material.

2.3.2.2. Deformation Crimping

In deformation crimping, crimp is produced by application of an external mechanical force. Deformation crimping is currently the most important method for texturing both staple fibers and filament yarns. Various techniques have been developed. The fibers can be crimped in a stuffer box (cf. Section 2.3.3) by knit-de-knit technique, or by feeding them through a pair

of gears (gear crimping). In another technique called edge crimping, the heated filaments are continuously drawn over a sharp edge. Mechanical force can also be applied by means of torsion (false-twist texturing cf. Section 3.3.2) or by allowing the filaments to pass through an air jet where the turbulence blows them together into a random structure (cf. Section 3.3.3).

2.3.2.3. Bicomponent Crimping

In bicomponent crimping, two polymers which usually differ in their chemical or physical properties are coextruded from a single spinneret capillary (Fig. 33A).

By using a suitable spinneret, the polymer components may be arranged side by side or in the form of a sheath – core structure. Figure 33B shows the structures of the resulting filaments. A stable, three-dimensional crimp is formed as a result of the different shrinkage and viscoelasticity of the polymers; it depends on the distribution of the polymer mass (e.g., 1 : 1 in the side-by-side arrangement or 3 : 7 in the sheath – core structure with an eccentric core).

2.3.3. Crimping of Staple Fibers and Filament Yarns

The stuffer box principle dominates in the crimping of staple fibers. Tow of up to 6×10^6 dtex is fed through two feed rollers at speeds of up to 8 m/s into a closed chamber called a stuffer box. This box may be equipped with a swivel flap to which a load can be applied (Fig. 34A), or entire upper and lower cover flaps can be closed pneumatically about a hingepoint (Fig. 34B).

Two delivery rollers push the tow into a chamber, and a folded plug builds up due to the forces and friction in the chamber. The fibers kink between the plug and the pinchpoint of the tow in the delivery rollers; a two-dimensional, sawtooth crimp is thus produced (Fig. 35). Crimp formation is determined by the roller and chamber geometry, the chamber pressure, and friction. Crimp stability is also affected by the temperature control of the feed material, the delivery rollers, and the chamber.

Figure 35. Tow with two-dimensional, sawtooth crimp

Many processes have been developed for texturing filament yarns, which include filament deformation, setting, and restoring of deformation in a continuous cycle. Different processes are used depending on the type of polymer and the filament fineness; they are described in Section 3.3.

2.4. Heat-Setting

2.4.1. Purpose

Drawn polymeric filaments have a high strength and elasticity, but when heated they begin to contract (i.e., shrink) at a certain temperature. This effect is enhanced in the presence of swelling agents such as water. These filaments are not generally suitable for use or further processing due to their lack of dimensional stability. Fabrics made from such filaments display, for example, poor crease resistance and poor shape retention during dyeing or washing. Therefore, the drawn filaments must be heat-set with or without a swelling agent and with or without tension. Shrinkage occurs during heat-setting and is accompanied by a simultaneous change in the fine structure mechanical properties of the filament. Since internal stresses are relieved, the fiber will not shrink during subsequent processing as long as the conditions are milder than those used for setting. However, a fiber should not be "heat-set to death" because while it is being processed into yarn, fabric, and finally, clothing, more extreme setting conditions must be used so that the article retains each new geometric shape imposed on it.

Definitions. If a filament or fiber of initial length l_0 is shortened to a length l by heat-setting or by the conditions of use, its shrinkage S and degree of setting F expressed in percent are defined as follows:

$$S = [(l_0 - l)/l_0] \times 100$$
$$F = (l/l_0) \times 100 = 100 - S$$

The degree of setting characterizes the dimensional stability of the fiber product under certain conditions of treatment and is, of course, greater if more presetting has occurred.

2.4.2. Mechanism

The dimensional stabilization of a synthetic fiber by heat-setting is made possible by the partial crystallinity of the polymers and the rearrangement of some of the crystalline regions in the amorphous matrix. The crystallites act as physical cross-links and are able to rearrange when the mobility of the molecular chains increases sufficiently during setting. Permanent, irreversible setting could otherwise only be produced by cross-linking the chains with covalent bonds as is the case, for example, in the vulcanization of rubber.

After being drawn, the fibers are generally not in thermodynamic equilibrium since stresses and thermally less stable crystallites are "frozen" in a colloidal structure. When this colloidal structure is heated to a temperature above the glass transition temperature (i.e., has a certain degree of thermal mobility), its thermodynamic equilibrium is characterized by a relative minimum in the free energy G. According to the laws of thermodynamics, G consists of the variables H (enthalpy) and S (entropy) [79]:

$$G(T,p,\sigma) = H(T,p,\sigma) - T \cdot S(T,p,\sigma)$$

where T, p and σ are the independent variables temperature, pressure, and (for a stretched fiber) tensile stress, respectively. The enthalpy H, in turn, consists of the internal energy U and the work content of the system:

$$H(T,p,\sigma) = U(T) + pV - \sigma V \ln(l/l_0)$$

where

$p\,V =$ pressure energy

$\sigma\,V \ln(l/l_0) = \sigma\,V\varepsilon_{\mathrm{H}} =$ stress energy

(V = volume and ε_{H} = Hencky measure of elongation related to the stress-free length l_0).

Stress energy is negative with respect to pressure energy because external energy is supplied to the system when the fiber length is extended ($l > l_0$), whereas the system must do compression work on the surroundings if expansion occurs in all directions.

When changes in state occur at constant pressure, the amount of heat exchanged with the surroundings is represented by ΔH; according to convention, ΔH is negative if heat passes from the system to the surroundings. For example, in the isochoric extension of a rubber band, the work of extension is liberated as heat and the rubber is temporarily warmed.

Hence, when a drawn polymeric fiber is heated above its glass transition temperature, it tends toward a more stable state by reducing its free enthalpy. This can be accomplished either by an increase in entropy (recoiling of chain segments) or by a decrease in enthalpy (by liberating heat due to crystallization, whereby U and pV decrease). Contrary to [80], however, the work of shrinkage performed in response to a tensile stress does not contribute to a decrease in enthalpy; on the contrary, in so doing the fiber would take up an equivalent amount of heat from the surroundings (Gough – Joule effect).

The amorphous matrix between the larger, more stable crystallites contains many small crystallites with some defects in ordering. Since stabilization can be achieved in two opposing ways, heat-setting entails a disproportionation of the colloidal structure (see Fig. 36) [80], and the amorphous matrix separates into two structural regions. On the one hand, the amorphous regions loosen due to relaxation of blocked stresses in the molecular chains (recoiling and displacement of segments); this is connected with the breakup of the least thermally stable, stressed crystallites and a certain amount of shrinkage. On the other hand, the more stable crystallites grow to form larger, more ordered regions which prevent further fiber shrinkage. An increase in the short-range order and/or degree of crystallinity can be measured by following the increase in average fiber density, which represents an interpolation between the density of the amorphous and crystalline regions. This two-phase

Figure 36. Colloidal structure of a polymeric filament
Crystalline regions indicated by thick lines

model is not, however, completely accurate because the packing density of the two phases can vary.

Figure 37. Stress – strain curves of poly(ethylene terephthalate) (PETP) filaments shrunk freely at different temperatures [12]
Filaments were heat-set without tension, shrinkage obtained during setting is indicated in parentheses

Effect of Stress on Heat-Setting. The minimum free energy, and hence optimal thermal stability, at the heat-setting temperature is obtained if the fiber can yield to the retractive force $(\partial G/\partial l)_T$ and is able to shrink freely [80]. The disadvantage of this alternative, however, is that the loosening of the amorphous regions flattens the stress – strain curve of the fiber (see Fig. 37). Tenacity at break decreases and elongation at break increases by approximately the amount of free shrinkage. In addition, the height of the elastic region is reduced by the formation of a flow saddle.

This deterioration of mechanical properties can be avoided by heat-setting the fiber at constant length under a force that opposes the shrinkage force (e.g., by setting on hot rollers immediately after continuous drawing). The orientation (i.e., entropy) and the stress – strain curve then remain practically unchanged [81]. Even without external shrinkage, the fiber can relax by means of internal creep due to its viscoelastic properties [82]. Crystallization then remains unaffected [81] or may even be enhanced if the applied stress is low because the

enthalpy – elastic portion of the restoring force is negative in the initial phase of extension [80]. However, because stresses applied at constant length do not completely relax to zero, a small amount of shrinkage takes place on unloading [80]. Because the heat-setting equilibrium attained under stress has a higher free enthalpy than that of the stress-free system, a certain residual shrinkage occurs when fibers are used or tested under stress-free conditions. The total shrinkage obtained after heat-setting under tension and heat treatment without tension is, however, much smaller than that obtained after heat-setting without applied tension [62], because the crystallites created under stress evidently stabilize the anisotropic composite structure more effectively. However, since the structure is only slightly loosened, properties such as dye uptake are also reduced.

Other Important Variables. If setting takes place in a medium which also acts as a swelling agent, the glass transition temperature is lowered by ΔT_g. This means that the temperature T at which setting is performed corresponds to an effective heat-setting temperature T_{eff} in an inert medium:

$$T_{eff} = T + \Delta T_g$$

Thus, for polyamides saturated with water, ΔT_g is approximately 80 °C [80]. This means that polyamide fibers must be heat-set in hot air without tension at a minimum temperature of 180 °C to be free of shrinkage when boiled in water without applied tension. Conversely, heat-setting in water at 100 °C provides resistance to shrinkage in hot air up to 180 °C. (For PETP, ΔT_g in water is ca. 30 °C [61].) Hence, drying can have a simultaneous heat-setting effect.

Other variables that affect the degree of thermal stabilization are the rate of heating (e.g., greater with saturated steam) and the residence time. If the rate of heating is too high, the setting shrinkage increases because disintegration of the unstable regions is more rapid than consolidation of the structure by postcrystallization. At higher setting temperatures, equilibrium is attained more quickly.

Effective Temperature and Effective Stress. The effective heat-setting temperature T_{eff} corresponds to the melting temperature of the crystallites formed in the matrix, which are relatively unstable compared to the main micelles. As discussed above, T_{eff} does not necessarily correspond to the actual temperature of treatment. At thermodynamic equilibrium of the crystalline – amorphous phase change ($\Delta G = 0$), the melting temperature T_m equals $\Delta H_m / \Delta S_m$ (ΔH_m and ΔS_m being the enthalpy and entropy of fusion, respectively). The enthalpy of fusion and hence the melting temperature are lower than for the overall melting of the fiber because the crystallites which are influenced by heat-setting are under tension; the internal energy of the matrix system is therefore not reduced fully during crystallization. Since melting of the crystallites is always associated with shrinkage, T_{eff} of a material can be determined in two ways: (1) by determining the onset of shrinkage on a shrinkage – temperature curve, and (2) by using differential scanning calorimetry (DSC). In addition to a major peak, the DSC diagram exhibits a smaller melting peak which appears at the effective temperature [83]. The heat of melting measured by DSC is also a measure of average crystallinity. Furthermore, stresses locked into the fiber and hence the effective stress of heat-setting, σ_{eff}, can also be determined by measuring the equilibrium shrinkage force [78], [83].

2.4.3. Shape Retention and Molecular Memory

Every solid with elastic properties is characterized by a stress-free reference state which is in thermodynamic equilibrium. Perturbation of this equilibrium by a mechanical strain ε at a temperature lower than the effective heat-setting temperature T_{eff} creates a restoring force which strives to reestablish the equilibrium. The stabilized structure, which represents a molecular memory of the equilibrium shape, has been called a *setting system*; the nonequilibrated shape with the perturbed molecular interaction has a been termed a *stressed system* because it generates stresses which strive toward the original shape [80]. Shape is not restricted merely to fiber length but includes all three dimensions,

e.g., crimp in the form of bends. If a fiber is bent forcibly, the outer, convex side is extended locally, whereas the inner, concave region is compressed. Because the fiber "remembers" its straight form (setting system 1, F 1) it normally straightens out when the force is removed. If deformation is conducted at a temperature higher than T_{eff}, the stressed system (stressed system 2, S 2) can be converted to molecular setting system 2 (F 2) by heat-setting (described in Section 2.4.2). At a higher temperature, sufficient energy of activation is available to obtain a minimum in the free energy; this transformation is thus irreversible and the memory of F 1 is erased and replaced by F 2. When the crimp is stressed mechanically, F 2 is transformed into a stressed system 3 (S 3). As long as deformation is reversible, crimp will later be restored. Even crimp which has been extended severely at a temperature below the glass transition temperature recovers when heated to a temperature higher than T_g but lower than T_{eff} because of its imprinted memory [80].

3. Manufacture of Filament Yarns

3.1. Melt Spinning of Filament Yarns

3.1.1. General Aspects

Multifilaments of polymeric materials were first produced by melt spinning in 1940. Subsequent developments have led to much higher operating speeds, throughputs, and product quality [84].

Spinning processes are categorized according to the processing speed and type of end product (Table 1). Speciality products may require speeds other than those listed here.

Depending on their production speed, the yarns have different properties, as can be seen in the strain – stress diagram (Fig. 38).

According to end use requirements, the luster of filaments is changed by modifying the cross section or by varying amount of dulling agent in the polymer. Spin dyeing by adding a suitable dye to the polymer prior to spinning is another possibility.

Figure 38. Stress – strain diagram for PETP produced at different production (winding) speeds
a) Undrawn yarn; b) Medium-oriented yarn; c) Partially oriented yarn; d) Highly oriented yarn; e) Fully drawn yarn

According to the application, yarns are produced in different counts and with different numbers of single filaments (Table 2).

3.1.2. Conventional Spinning

Spinning systems are generally arranged to give a vertical downward process flow over several floors, as shown in Figure 39 [61]. In the *chips spinning process*, polymer chips are brought to the required state of dryness by batchwise or continuous drying. They are then fed pneumatically to the chips silo (a) from where they fall by gravity into the feeding opening of the extruder (b). The chips are transported by the rotating extruder screw (feeding zone) and melted between the electrically heated barrel and the screw (melting zone). Adequate pressure and uniform output of the polymer is obtained by means of a progressive increase in the core diameter of the screw (metering zone). The speed of the screw is controlled to ensure that the melt is fed to the distribution line (d) at constant pressure even if the consumption of the spinning machine varies.

In the direct spinning process, the liquid polymer is fed from the polycondensation stage directly to the distribution line (d) via a pressure pump; the solid-phase stages of chips cutting and drying are omitted.

Polymer of insufficient purity is prefiltered by means of a main melt filter (c). The filter inserts can be changed semi- or fully automatically when their service life is over without disturbing the spinning process. Metal filters, sintered metals, and powdered metal, or silicic materials

Table 1. Classification of spinning processes

Yarn type	Description	Processing speed, m/s	Processing speed, m/min	Product
UDY	undrawn yarn	8 – 30	500 – 1800	intermediate
MOY	medium-oriented yarn	28 – 43	1700 – 2600	intermediate
POY	partially oriented yarn	43 – 83	2600 – 5000	intermediate
HOY	highly oriented yarn	83 – 100	5500 – 7500	final
FDY	fully drawn yarn	75 – 83	4500 – 6500	final

Table 2. Classification of yarns

Class of filament	Titer per single filament, dtex	Number of filaments	Total filament count, dtex
Monofil (textile)	7 – 20	1 – 3	10 – 22
Regular	2 – 6	7 – 72	22 – 167
High-count	1 – 2	48 – 120	55 – 167
Microfilament	0,5 – 0.99	48 – 192	55 – 167
Superfine filaments	< 0.5	120 – 384	55 – 167

with a defined pore size are used as filter media; a combination of woven and nonwoven metal filters is usually preferred.

The melt distribution line (d) carries the polymer with equal residence times to the spin heads in the spin beam (e). Each spin head contains all the elements for the preparation of the melt and formation of the filaments. Individual spin heads can be shut down by means of freezing or mechanical valves if servicing of the spin pump is required. The spinning system is vapor-heated (g) using a mixture of diphenyl – diphenyl oxide ($bp = 256\,°C$). For different temperatures, a corresponding over- or underpressure is maintained. The vapor is generated by an electrically heated boiler which may be separate or integrated into the lower section of the spin beam.

In the spin beam, the melt stream is carried to multiple gear pumps (f) where it is metered and conveyed to the spin pack (h) at a spinning pressure of 5 – 40 MPa. In the spin pack the melt is filtered, homogenized, and transported to the spinneret which contains the desired number of capillaries (3 – 350) with a circular or shaped cross section. Depending on the polymer, filament fineness, and spinning speed, the diameter of the capillary holes is 0.15 – 0.8 mm and the capillary length one to five times their diameter. Filtration is performed with the same filter media as described above for the main melt filter, a combination of different filter media may also be employed. As a rule, at a single spinning position several yarn ends (2 – 16) are spun, quenched, finished, and wound up either together or in two groups. Several spinning positions producing the same product are combined into a spinning machine (cf. Fig. 40). The spin packs have a limited service life and can be changed after stopping the relevant spin pump.

The liquid filaments emerge vertically from the spinneret and are cooled to room temperature by using transverse or radially blown air with a temperature of 18 – 26 °C and a relative humidity of 50 – 70 % (i). Depending on the process and the production schedule, the length of the blow-air zone is 25 – 180 cm and the air velocity ranges from 0.25 to 1.2 m/s. The cooled yarn ends are guided vertically to the take-up by the conditioner (j). The take-up (Fig. 40) contains all the elements needed for the posttreatment and winding of the yarn.

A film of finish is applied either after the yarn is cooled in the quenching duct [Fig. 39 (i)] or when it leaves the conditioner [Fig. 39 (j)] at the take-up [Fig. 39 (k)]. The finish consists of a mixture of mineral and/or ester oils and emulsifiers which improve the cohesion of the filaments, as well as their electrostatic and frictional properties. The yarn is covered with a film of finish by running it tangentially over a ceramic roller which rotates at a constant speed in a trough containing the finishing oil [Fig. 39 (k)]. Several yarns can be finished simultaneously with one roller. A more precise method of applying finish involves metering the finish for each yarn by means of a gear pump and a ceramic applicator pin. The amount of finish applied is determined by the speed of the rollers

and pumps. The finishing oil can be emulsified in water, dissolved, or used neat.

As shown in Figure 39, the finished yarn ends pass over two godets (l), which determine the spinning speed, and are then led to the winder. The yarn is wound by means of a traversing guide (m) onto cylindrical cardboard or resin tubes to form spinning bobbins (n). A friction roller ensures that the speed of the tube with its wound yarn remains constant. The increase in diameter of the bobbin is compensated by backward motion of the winding head with the friction roller or of the chuck bearing the wound yarn. Traverse motion is usually performed by a simple cam-shaft traversing systems that moves a ceramic guide along the bobbins stroke. The traverse speed is modulated at frequent intervals to prevent slippage of yarn layers when package patterns are formed due to an even-number ratio between the rates of bobbin rotation and traverse. The yarn is threaded into the take-up

by means of a movable injector gun powered by compressed air.

Undrawn yarn (UDY) is wound at 8 – 30 m/s and has a low orientation (LOY). It can only be stored for short periods and must be drawn three to four times in a subsequent drawing process to obtain a product with properties that are suitable for its end use [2], [61], [84]. To attain high yarn strength for industrial uses, the yarn is passed through a heated tube with a length of ca. 30 cm (hood heater) after the spinneret.

Auxilliary plants are necessary to provide auxilliaries, raw materials etc. in the required quality neccesary for production of the filaments:

- Chips drying to adjust water content (if extruder spinning is used)
- Spin-pack, spin-pump, and melt-filter cleaning and servicing
- Spin-finish make-up
- Winder maintenance
- Quality control for raw material and final product

3.1.3. High-Speed Spinning

Since 1970, spinning at conventional winding speeds of 8 – 30 m/s has been replaced in many areas by high-speed spinning with winding speeds of 43 – 75 m/s. High-speed spinning yields a partially oriented yarn (POY) which subsequently has to be drawn 1.2- to 2.2-fold for further use. Since POY has a higher degree of orientation than UDY, it has a longer storage life and further external processing (e.g., texturing) is thus possible. In general, a higher productivity per spinneret is achieved (see Fig. 31). The higher initial modulus makes POY less delicate than UDY; higher operating speeds and yields are therefore possible in subsequent processing.

High-speed spinning proceeds basically as described in Section 3.1.2; a typical spinning unit is shown in Figure 41. As a result of the high operating speed, higher demands are made on the polymer itself, its handling, its filtration, and the equipment. The increased take-off speed results in a comparatively high yarn winding tension so that godets may be required to control winding tension especially for high count and low-dtex single yarns.

After quenching, a finish is normally applied at a variable distance (50 – 200 cm) below the spinneret to control yarn tension. Finish is usually applied by means of applicator pins and metering pumps.

The yarn is frequently interlaced immediately before winding to improve yarn take-off from the package. The individual filaments are entangled by directing the yarn past a nozzle made of sintered ceramic which emits a jet of compressed air at a pressure of 0.3 – 0.6 MPa [2], [86].

The yarn is finally wound on specially developed high-speed winders which nowadays usually are equipped with automatic doffing (changing) devices (Fig. 42). Automatic winders operate practically without waste and are labor-saving. Often they are combined with an automatic doffing system which removes the full

Figure 42. Automatic doffing system for unloading the full bobbins from the winder
Coutesy of Toray Engineering Co., Ltd.

bobbins from the winder and replace them with empty tubes.

The bobbin chuck is usually driven directly by a motor (axle drive). The peripheral speed of the bobbin is kept constant by controlling either the number of revolutions of a friction-driven sensor roll or by means of the yarn winding tension (godet machines only). The yarn is distributed over the traverse stroke by means of a shuttlelike moving traversing guide onto cylindrical cardboard or for higher speeds with the aid of two or more opposing rotors over the width of the traverse (Fig. 43)[88]. One winder is capable of simultaneously producing two to ten packages on one chuck with a weight of 8 – 40 kg, depending on the number of ends.

To ensure good package formation and unwinding conditions, traverse modulation (see Section 3.1.2) can be supplemented by a step precision winding unit which changes the traverse speed by means of a microprocessor [89]. Typical winding speed is 50 m/s for PETP POY, with modified polymer 83 m/s, and for Nylon POY 70 m/s.

3.1.4. Superhigh-Speed Spinning

Since about 1980, yarn with increased orientation has been obtained by increasing the winding speed above 83 m/s to 133 m/s; 117 m/s is the maximum speed used commercially. The product is a flat yarn which usually requires no further drawing. The yarn displays a lower strength, lower initial modulus, and higher elongation in comparison to mechanically drawn yarn. In the case of PETP the boil-off-shrinkage of the yarn is much lower, too. The modified yarn properties result in a limited application window for this product.

Production is basically the same as that described in Sections 3.1.2 and 3.1.3, but greater demands are made on the equipment and the polymer because of the extremely high operating speeds. The yarn is spun without mecanical drawing, and final elongation is determined by take-up speed and the titer of single filaments. Tension control with godets is necessary if a spinning machine of conventional height is used. In compact spinning [85], omission of the conditioner between the quenching zone and the winder reduces the height of the spinning unit from ca. 12 m (conventional height) to ca. 6 m. This decrease, mainly in the thread-pass length, reduces yarn tension by lowering the air drag, so that godets can be dispensed with.

Figure 43. Eight-end winder with an automatic doffing system for 2500 – 6000 m/min with rotating traverse system Courtesy of Murata Machinery Ltd., Osaka, Japan

The yarn may also be reheated in a heating tube 1 – 3 m in length immediately after quenching to obtain a further increase in orientation [87]. Two open, looped godets are used in this case to control yarn tension. Due to the very high yarn speed, only winders with a rotating traverse system are in use for this process (cf. Fig. 43) [88].

To ensure good unwinding conditions, traverse modulation (see Section 3.1.3) can be supplemented by a step precision winding unit which changes the traverse speed by means of a microprocessor [89]. To improve cohesion and take-off properties, the yarn is commonly interlaced as described in Section 3.1.2. Because of the high speeds involved, manual string up is performed at lower speeds by means of an injector, after which operating speed is reached automatically, and an automatic doff is used to segregate yarn with unsuitable operating speed. Further doffs are carried out automatically at full operating speed [2].

3.1.5. Draw Twisting and Draw Winding

The final properties of low-oriented yarns, produced as described in Section 3.1.2 and 3.1.3, are established by subsequent drawing. Drawing results in higher strength, lower elongation at break, and in some cases, lower boil-off and hot-air shrinkage (drawing is discussed in detail in Section 2.2). The final product is a flat yarn with suitable properties for weaving, knitting, and industrial applications. In *draw twisting,* the yarn is simultaneously drawn and twisted, whereas in *draw winding* it is simply drawn and wound.

In many areas drawing machines have been replaced by integrated, high-speed processes due to their lower labor costs and their higher yarn quality and outputs, as described in Section 3.1.8.

The path of the yarn in the drawing machine can differ depending on the polymer used. Figure 44 shows the path for PETP, for which the hot plate (g) and the second godet (e) are heated, while the other godets are cold. For nylon 6 and nylon 66, which are drawn cold [84], [90], the hot plate and second godet are omitted. A draw ratio of 1/1.2 to 1/5 is applied between rollers (a), (c), and (e) for PETP, and between (a) and (c) for nylon. The yarn is directed onto the cop (i) by a ring (j) that moves up and down and holds a traveler (k). The traveler is pulled along the ring by the yarn-winding tension. The difference between the speeds of the traveler and the cop twists the yarn while it is being wound (draw twisting). Yarn buildup on the cop (i) is programmed, the most common patterns being

differential, cop, and parallel winding. The take-up speed is 12 – 24 m/s for textile yarn [2].

Figure 45. Draw winding machine with two godets and a hot plate, two ends per position
Courtesy of Zinser Synthetic Systems, Germany

Draw winding is carried out similarly, but instead of being twisted the yarn is wound onto cylindrical packages rather than biconical cops by using a winder at each drawing position. The wound yarn is practically free of twist. Take-up speed is 20 – 28 m/s; on some machines up to 33 m/s is possible. The temperature of the draw rollers and heaters is monitored by scanners. Interlacing of the yarn before winding (cf. Section 3.1.3) is often used to improve cohesion, especially in draw winding.

Industrial yarns are processed on draw winding machines of reinforced design, similar to that illustrated in Figure 45. Depending on the end use of the yarn, the machine may have up to three drawing zones, three hot draw rollers, three drawing pins, and two hot plates in the drawing fields. The total draw ratio can be as high as 1/7. Take up of the yarn and interlacing is as described above. The take-up speed is 3 – 13 m/s [2].

Most industrial yarn nowadays is produced by one-step processes; speciality products are still produced by draw winding or draw twisting.

3.1.6. Draw Warping

Undrawn or partially drawn textile filament yarn, produced as described in Sections 3.1.2 and 3.1.3, is subjected to integrated drawing and warping to produce section beams for use in knitting and weaving. The drawing process described in Section 3.1.5 is then omitted. The feed yarn must be of above-average quality to minimize machine stops and any resultant dyeing defects.

Draw warping is illustrated schematically in Figure 46. The yarn is taken off 600 – 1400 bobbins arranged in a creel (a) and fed into the drawing unit as a warp via yarn brakes and a reed with eyelets (f). A series of seven to ten sets of rollers with S loops are arranged in three groups (b) – (d) to form a drawing zone (draw ratio 1 : 1.2 to 1 : 5) and a relaxation zone. Drawing can also be assisted by incorporating a heated water bath, a heated draw pin, or heated feed rollers in the drawing zone. The yarn warp is then heat-set by guiding it over a hot plate (e). Yarn defects (slubs) are located by means of optical detectors (g); the unit is stopped automatically so that defects can be removed. To minimize damage to the yarn during machine stoppage, the hot plate is swung out of the way, the heated rollers are cooled, and the draw pins are rotated so that the yarn is in contact with the unheated side. Yarn cohesion is improved by applying a finishing oil by means of a wetted roller rotating in a trough (h). Yarn cohesion is further improved by interlacing the yarns with an entangling reed (f) be-

fore the oil is applied; the filaments of one yarn end are interlaced as they pass a jet supplied with compressed air at a pressure of 0.3 – 0.6 MPa. Some machines are equiped with a sizing process instead to improve yarn cohesion further for delicate yarns that are to be woven. The finished yarn is wound under constant winding tension at speeds up to 10 m/s to form a section beam (i). Sized yarn is wound at speeds of up to 3.3 m/s [93–96].

3.1.7. Horizontal Drawing

Undrawn or partially drawn yarn [92], produced as described in Sections 3.1.2 and 3.1.3, can also acquire its final properties in the form of a warp on a multi-end drawing machine rather than a draw twister. Horizontal drawing is used primarily to process industrial yarn. Since a relatively low drawing speed is used (2 – 8 m/s), yarns with very low shrinkage are obtained due to the comparatively high residence time in the machine's heater.

The yarn ends are drawn off a large number of bobbins placed in a creel and are then fed into the drawing unit as a warp. The drawing unit consists of five to nine open, heated feed rollers and a subsequent, similarly constructed set of draw rollers with 1.2 – 7-fold greater surface speed. The warp is looped around the two sets of rollers and drawn as a result of their different speeds. Hot-air shrinkage of the yarn is reduced to the desired value by heating it in a channel between the draw rollers. The yarn is then looped around a third, unheated set of draw rollers with three to seven open, looped feed rollers; these rollers run at a slower speed than the previous set and thus permit a defined relaxation of the yarn. The yarn is cross-wound on cylindrical bobbins in a bobbin creel. The speed of the winders is con-

trolled by yarn tension. A yarn take-up unit is shown in Figure 47. If necessary, yarn cohesion can be improved by interlacing individual yarn filaments or by applying a finishing oil as described in Section 3.1.6.

3.1.8. Spin Drawing

In spin drawing, the spinning and drawing processes described in Sections 3.1.2, 3.1.3, and 3.1.5 are combined into a one-step process which produces a flat, ready-to-use, fully drawn yarn (FDY) for textile or industrial purposes. Spin drawing has largely replaced the conventional two-step process because it is less labor-intensive, quality control costs are lower, and a better quality yarn is produced. A spin-drawing machine is shown in Figure 48.

Figure 48. Spin-drawing machine for industrial yarns, with four ends per spinning position
Courtesy of Rieter, Winterthur, Switzerland

For textile application spinning is carried out as described in Sections 3.1.2 and 3.1.3. In the 1970s conventional spinning speeds of up to 17 m/s and winding speeds of ca. 67 m/s were used. Today, high-speed spinning at 37 – 75 m/s with winding speeds of 70 – 83 m/s is preferred; this results in higher throughput and more uniform quality. After finish has been applied, the yarn is looped several times around a feed godet with an idler roll or around a pair of godets. The feed godet may be heated inductively if necessary (e.g., in the case of PETP). A second, similarly constructed drawing unit runs 1.2 – 4 times faster (the draw ratio), at a temperature of 130 – 180 °C. This unit draws the yarn, relaxes it, and allows thermal shrinkage to be adjusted to the desired value.

If processing speed is sufficiently high, the godets do not necessarily have to be heated, relaxation of the yarn prior to winding (e.g., by means of steam) is sufficient [97].

In the production of industrial yarn, the spinning speed is usually 7 – 12 m/s. Three to four sets of godets are needed so that a total draw ratio of 1/5 to 1/7 is obtained in two drawing steps. The temperature of the godets is between 80 and 220 °C. A final drawing zone with a draw ratio between 1/0.85 and 1/1.05, serves as a relaxation zone. The yarns are interlaced as described in Section 3.1.4 to improve their cohesion for further processing [2]. For the production of industrial yarn according to the HMLS (high-modus, low-shrinkage) process, spinning speed is between 30 and 38 m/s. Three to four sets of godets are used for a total draw ratio between 1.18 and 1.22. Winding speed is between 93 and 108 m/s.

3.2. Solution Spinning of Filament Yarns

The basic principles of solution spinning are described in Section 2.1.4. Examples of polymers which are spun commercially into filament yarn from solutions are polyacrylonitrile and its copolymers [98], poly(vinyl alcohol) [99], and aramids [2]. Filament yarns with high heat resistance, a high modulus of elasticity, and/or a high strength (tenacity) have also been introduced. These yarns are made from polybenzimidazole, poly(amide – imide), polyoxydiazole, polytriazole, and other special polymers [2] and can be produced only by solution spinning.

Economic preferences for wet or dry spinning cannot be generally defined because process economics depend strongly on use of the optimal solvent. The required properties of the filament yarn may also influence the choice of process. In the case of poly(vinyl alcohol), for example, silklike yarn is obtained by dry spinning [100], whereas wet spinning produces high-strength, high-modulus yarns [101].

Figure 49. Schematic of a dry-spinning shaft
a) Spin pump; b) Spinneret; c) Filament yarn; d) Drying chamber; e) Take-up roller; f) Inlet for drying gas; g) Outlet for drying gas and solvent vapor

3.2.1. Dry Spinning

Strict requirements are placed on the solvents used in dry spinning. In addition to being excellent solvents for the polymer in question, they must be nontoxic, and must have a low heat of evaporation, and a low risk of explosion. The spinning solutions can be prepared continuously or batchwise in commercial solubilizers, kneaders, or screws. Solutions should be as concentrated as possible and may contain up to 45 wt % of solid material, depending on the polymer and its degree of polymerization. The highly viscous spinning solution is filtered and degassed; it is then conveyed, if necessary in heated pipes, to the spin pumps and the spinnerets by means of extruders or gear pumps. The spin pumps and spinnerets are located in the upper part of a spinning shaft, which is shown schematically in Figure 49. The shaft is 4 – 8 m long and consists of a vertical, double-jacketed, heated duct fitted with an inlet and an outlet for the drying gas. The drying gas (air or an inert gas) is heated to a temperature corresponding to the boiling point of the solvent; gas flow is either cocurrent or countercurrent with respect to the spun filaments. To avoid fluctuations in quality of the filament yarn, all spinning parameters must be kept constant within a narrow range. Optimal recovery of solvent is an extremely important economic factor in fiber production. The filaments emerging from the dry-spinning shaft are rerouted by take-off rolls, coated with finish, and wound at speeds of up to 17 m/s. Further processing of the spun material is analogous to that described in Section 3.1.5. As a rule, 12 to 64 dry-spinning shafts are arranged side by side in series and constitute a unit known as a spinning machine.

3.2.2. Wet Spinning

The principles of wet spinning are described in Section 2.1.4.2. Preparation and purification of the highly concentrated spinning solution are similar to dry spinning. The viscosity and therefore the concentration of the polymer are selected to suit the requirements of the spinning units and to give a pressure at the spin pump of ca. 1 – 2 MPa. The spinning solution is filtered and conveyed to the spinnerets; a number of spinnerets generally spin into a common coagulating bath. The coagulation conditions are an extremely important factor in determining the solidification of the swollen, gel-like filaments and therefore the filament quality. Immense know-how is required to maintain a constant concentration and temperature in the coagulating bath during spinning. The residence time of the yarn in the coagulating bath is affected by a number of factors, such as speed of injection and drawoff, and must be optimized to ensure uniform, flawless coagulation of the yarn.

In older units, yarn from the coagulating bath is subjected to drawing and posttreatment in separate processes, but modern integrated units operate continuously in a one-step mode, as shown in Figure 50. Filament yarns from many neighboring spinnerets are drawn from the coagulating bath and stretched by warp drawing. They are then posttreated and wound at speeds of 2.5 – 15 m/s on cylindrical bobbins on individual winders combined in creels. Posttreatment

such as drying, drawing, and heat-setting differs depending on the polymer being processed and the desired properties of the filament yarn. The drawing unit for warp drawing shown in Figure 50 is designed for the production of high-strength, high-modulus poly(vinyl alcohol) yarn [102].

Gel Spinning. Gel spinning is a type of solution spinning that has been defined as as dry spinning at a very high polymer concentration (up to 80 %), that is, a cross between dry and melt spinning. However, the term is also used because of the gel-like appearance of the resulting filaments [67], [103].

This spinning technology was developed at the end of the 1970s [104] for the production of high-performance polyethylene fibers and filament yarns which are distinguished by high strength and high modulus of elasticity. These special properties are achieved because gel spinning orients the macromolecular polymer chains along the fiber axis with a high degree of parallelism. Polyethylene with an extremely high molecular mass ($\bar{M}_w > 10^6$ g/mol) is used and must be spun from solutions at a relatively low concentration. Under these conditions, the molecular chains uncoil and can orient themselves along the fiber axis before crystallization sets in. The polymer solution (ca. 20 wt %) is prepared in a hydrocarbon solvent such as Decalin (decahydronaphthalene [*91-17-8*]) and then forced through the spinnerets at 120–130 °C and spun in a dry-spinning shaft. Spinning is followed by hot drawing at 70–150 °C.

High-performance polyethylene fibers produced by gel spinning are being introduced commercially under the trade name DYNEEMA [103]. Other polymers, such as polyacrylonitrile, are also assumed to be accessible to gel spinning and the manufacture of high-performance fibers.

3.3. Texturing of Filament Yarns

3.3.1. Development of Texturing Processes

In many applications, the original smooth multifilament yarns must be textured (crimped) in two or three dimensions so that they acquire the optimum properties required for their end use (cf. Section 2.3). Texturing increases the bulk and improves the elasticity of the yarn. Only a few of the many texturing processes developed during the 1950s and 1960s have survived on a commercial scale [2], [105]. For textile titers in the range 22–330 dtex, *false-twist texturing* is now used for more than 90 % of all polyesters and polyamides; twist texturing, air texturing, and bicomponent technology are only of minor importance. During the past ten years, textured polyester filament yarns have been primarily responsible for the growing popularity of *friction false-twist texturing*. Worldwide production of textured polyester yarn is anticipated to be 3.0×10^6 t/a by 1993, which is much more than the total annual worldwide consumption of wool. Further strong increases up to the year 2000 are only expected in Asia. In 1997 about 79 % of 179 176 friction false twist texturing spindles were shipped to Asia [20].

Until the early 1970s, three separate process steps were required to produce textured filament yarn. The yarn was melt-spun conventionally at a draw-off speed of 13–25 m/s; it was then drawn on draw twisters or draw winders and, finally, textured on special machines. Since 1972, however, the combined one-step draw-texturing process has become increasingly important worldwide. Compared to the conventional three-step process, this technology results not only in remarkable improvements in the quality of the textured yarn but also in substantial financial savings. The pneumatic stuffer box has increasingly replaced the mechanical stuffer box in the production of textured yarns with a fineness of 1000–≥4000 dtex; these so-called bulked continuous-filament (BCF) yarns are used for carpets and for decorative or upholstery fabric.

3.3.2. False-Twist Texturing

In false-twist texturing, thermoplastic multifilaments are twisted by torsion, the twist is heat-set, and the yarns are subsequently detwisted in a continuous process. Textured yarns are obtained which exhibit good bulk but are almost completely free of twist. Also since 1972, false-twist texturing on spindles has largely been replaced by texturing in which twist is imparted by friction. Friction texturing allows considerably greater productivity because drawoff speeds of

Figure 50. Schematic of a wet-spinning – warp-drawing machine

Figure 51. Draw-texturing process
A) Sequential draw texturing; B) Simultaneous draw texturing

10 – 20 m/s can be obtained; texturing on spindles only allowed a maximum draw-off speed of 5 m/s. The rapid development of friction texturing would not have been possible without the commercial introduction of high-speed spinning and draw texturing [108].

Draw texturing may be either sequential or simultaneous (see Fig. 51). In sequential draw texturing, the yarn is drawn in a drawing zone which precedes the texturing zone; in simultaneous draw texturing, drawing and texturing are integrated in a single zone.

High-speed spinning of partially oriented yarn (POY) in combination with simultaneous draw texturing has made its mark worldwide in the manufacture of polyester yarns. Depending on whether the crimp of textured yarns is reduced by thermal treatment, the yarns are divided into non-heat-set, highly elastic (HE) yarns with a crimp of 35 – 50 % and heat-set yarns with a 20 – 25 % crimp. Since worldwide capacity for conventionally spun polyamide yarns with a low orientation (LOY) is still existing, these polyamide yarns are usually crimped by sequential draw texturing. New installations for the manufacture of polyamide yarn employ high-speed spinning so that the resultant POY is also subjected to simultaneous draw texturing.

Commercial frictional draw-texturing machines are based on a similar design. They all contain the following essential elements: a supply creel, heater, cooler, friction-texturing unit, and winding unit. A typical draw-texturing machine is depicted in Figure 52.

Figure 52. Double-heater draw-texturing machine

Yarn runs from the POY bobbins mounted on the supply creel (a) to feed rollers (c), over the primary heater (e) and cooling plate (f) to the frictional texturing unit (g) and a second set of feed rollers (c). In the case of heat-set yarn, the drawn and textured filaments pass over a secondary heater (j) before being wound in the take-up unit (k). To attain favorable properties for further processing, the cohesion of the textured yarn must be improved. For economic reasons, textured yarns are interlaced rather than twisted immediately after draw texturing.

Table 3. Advantages and disadvantages of disk materials

	Ceramic disks	Polyurethane disks
Tenacity of textured yarn	lower	higher
Sensitivity to spin finish	lower	higher
Snow generation	higher	lower
Crimp	lower	higher
Lifetime	long	shorter
Costs	lower	higher

Disk-friction units with three axes, (see Fig. 53) are commonly used to impart twist, the disks can be made of pure ceramic or polyurethane, as well as steel or aluminium, coated with different materials. These different disk materials have different advantages and disadvantages which are summerized in Table 3.

A draw-texturing machine is shown in Figure 54.

The number of disks on a draw texturing unit depends on production speed, yarn thickness, disk surface and spin-finish content. Usually this number varries from four to eight. Sometimes also polished disks are used at the top and the end of a disk arrangement.

Two alternative twisters based on the principle of nip-controlled vector (NCV) drive have been developed by Murata Machinery (Japan) and Barmag (Germany). In these machines, twist is imposed on the yarn by two elastic surfaces running in opposite directions. Only Murata Machinery has commercialized the texturizing unit with crossed belts and one large disk with two belts (one on each side of the disk).

The Murata system uses small intersecting elastic belts (Fig. 55), and the Barmag Ringtex system textures the yarn between two intersecting, ring-shaped friction surfaces (Fig. 56). The NVC false-twist systems are said to per-

mit higher texturing speed, reduce abrasion loss, improve yarn strength, and be generally gentler. However, because of its better process stability the frictional draw-texturing process has more widely established in the textile industry.

Figure 53. Disk-friction false twister with three axes

Typical lengths of heating zones are about 2 – 2.5 m each. To minimize the machine height and to improve the operation of the machine, different yarn paths have been realized. Figure 52 shows a so-called collapsed or folded yarn running path. However, rerouting the yarn can be detrimental to yarn quality, especially in the case of profiled or very fine filaments. To improve the texturing performance, different machine designs are available, as shown in Figure 57.

Attempts are being made to obtain even higher texturing speeds for economic reasons. Therefore, noncontact high-temperature heaters were developed. Such heaters operated at about 400 °C as opposed to the temperature of standard contact heater of about 200 °C. The high-temperature noncontact heaters are shorter and so the yarn tension caused by friction is much lower, especially at high speeds. With such heaters special care must be taken with the spin finish, since small deposits of heat-cracked spin finish in the heater can limit the operation drastically.

To guarantee a uniform and failure-free quality of the textured yarn, new machines are equipped with an online quality inspection system. Such systems monitor the yarn tension of each yarn path and classify each bobbin into different levels of quality. In combination with an automatic doffing system, such systems reduce costs by decreasing labor requirements and allowing night shifts without personnel.

Figure 54. Draw-texturing machine (Mach Crimper 33H) Courtesy of Murata Machinery, Japan

Attempts are also being made to produce POY-bobbins with better runoff properties. Barmag has, for example, introduced the ribbon-free random wind (RFR) system [109].

3.3.3. Air-Jet Texturing

Widespread use of air-jet texturing was hindered by its high consumption of air and the relatively low production speed (ca. 2 m/s). In the 1970s, however, production speed was successfully increased (7 – 10 m/s) and air consumption reduced. These developments, together with the trend to yarn with a character more like that of staple fibers, have led to increased use of air-jet texturing.

Figure 55. Double-belt false twister

Figure 56. Disk-friction false twister (Ringtex system)
A) Small twist angle, low degree of twisting; B) Large twist angle, high degree of twisting

In air-jet texturing, one or more multifilament yarns are fed into the texturing jet where they are swirled in a turbulent stream of air and form loops and curls. This process is illustrated schematically in Figure 58. The basic mechanism of air-jet texturing involves mechanical deformation of individual filaments [110]; it can therefore be used to texture both thermoplastic and nonthermoplastic filaments.

The construction of air-jet texturing machines is similar to that of false-twist texturing machines (see Section 3.3.2), but an air-texturing jet replaces the false twisting unit. Since air-jet texturing machines can be fed with both drawn and undrawn (POY or LOY) filament yarns, they are equipped with one or two drawing zones that precede the texturing zone [111–113].

The crimp character of an air jet textured yarn is much different to that of a friction false twisted textured yarn. The two types of textured yarn are

used in different fields of application in the textile industry.

3.3.4. Stuffer Box Texturing

In the mechanical stuffer box process (shown schematically in Fig. 59), texturing is achieved by using a set of rollers to feed the filament yarn into a heated, pressure-controlled stuffer box. The yarn undergoes buckling deformation, and a sawtooth, two-dimensional crimp is formed [114]. Stuffer-box crimped yarns up to 330 dtex are of minor commercial importance for textile applications. The pneumatic stuffer box has almost completely replaced the mechanical stuffer box for texturing coarser yarns with a fineness of ca. 500 – 3300 dtex, which are primarily made of polyamides or polypropylene. The major reasons for this are probably the substantially higher texturing speed of up to 67 m/s and the three-dimensional crimp which is far superior in bulk and volume to the sawtooth, two dimensional crimp. The basic principle of the pneumatic stuffer box was described in a patent application in 1957 [115]. The system is shown schematically in Figure 60.

Two different process variants are available for the production of textured BCF yarn with a fineness of 1000 – $\geq$ 4000 dtex for the carpet and upholstery industries: discontinuous draw texturing and continuous spin-draw texturing [116–118].

Discontinuous draw texturing consists of two steps. The undrawn filaments are first spun on conventional spinning units and wound to give cylindrical bobbins with weights of ca. 20 – 50 kg. In a second step, the spun bobbins are then placed in supply creels, and the individual filament yarns are conveyed to the individual positions of the draw-texturing machine via yarn guides and brakes. A typical draw-texturing machine is shown in Figure 61.

The draw unit of the machine consists of a system of heated godets formed either by pairs of rollers or by feed rollers with idler rolls. After being drawn, the filament yarn is textured in a pneumatic stuffer box, deposited on cooling drums, and subsequently wound on cylindrical bobbins. As a rule, the textured yarn is also interlaced prior to winding to improve its processing characteristics. One to four yarn ends can be processed simultaneously at each machine position, i.e., in each draw-texturing unit. One- and two-end operations are carried out commercially at up to 67 m/s, but the speed must be reduced to 42 – 50 m/s in four-end operations.

Figure 60. Pneumatic stuffer box crimping [115]
a) Yarn; b) Heated air; c) Injection tube; d) Stuffer box; e) Partition for separating air flow; f) Cold gas; g) Setting zone with air-permeable walls; h) Crimped yarn

The discontinuous, two-step process is particularly suited to the manufacture of speciality BCF yarns. Various spun-dyed filament yarns of different fineness or different dyeing properties can be plied and processed together in a single texturing chamber to give special BCF yarns.

The high texturing speed attainable with the pneumatic stuffer box system allows the spinning of the filament yarn and draw texturing to be combined in a highly economical, single-step, *continuous spin-draw texturing process.* A spin-

draw texturing machine is shown schematically in Figure 62; the draw-texturing unit is located directly below the conditioner of the spinning machine. The spun filament yarns are drawn immediately, textured, interlaced, and usually wound at a rate of 50 – 67 m/s by automatic winders.

Figure 61. Draw-texturing machine with four ends for bulked continuous-filament (BCF) yarn
Courtesy of Rieter, Winterthur, Switzerland

3.3.5. Bistructural Texturing

In bistructural texturing, also called spin texturing, the latent crimp present in the spun yarn is activated by a process known as development [119], [120] (see also Section 2.3.2.1). Texture can be developed by means of thermal or hydrothermal treatment either during or after separate drawing [121]. Alternatively, texture development can occur during dyeing or heat-setting after the smooth yarn has been processed into textiles [122]. Spinning, drawing, texture development, and winding can also be integrated into a one-step process [123]. In Section 2.3.2.1 a number of processes are described which can be used to produce anisotropic filament structures that lead to spin-textured yarns. These processes are all based on the inhomogeneity of the yarn material in the cross-sectional plane of the individual filaments. Differences in the shrinkage of the individual filaments, caused by chemical or physical inhomogenity, are primarily responsible for the formation of three-dimensional crimp. This method of texturing allows the two-step process technology of high-speed spinning and subsequent draw texturing (described in Section 3.3.2) to be developed into a totally integrated, one-step process.

Figure 62. One-step, spin-draw texturing machine for nylon 6, bulked continuous-filament (BCF) yarn
a) Extruder; b) Motor and gears ; c) Spin beam; d) Quenching system; e) Conditioner; f) Drawing, texturing, and winding systems

However, spin texturing is not widely used in industry (contrary to earlier expectations) [119], [124]. The reason for this could be that bicomponent technology has been predominantly used to produce bistructurally textured multifilament yarns. This technique involves the simultaneous spinning of two polymers and is much more demanding and also more expen-

sive than spinning a single polymer. In addition, bistructurally textured multifilament yarns differ in hand (touch) and appearance (crimp) from the friction-textured yarns that currently dominate the market and have therefore had difficulty in being accepted. Especially for polyesters (which represent about 80 – 90 % of world textured yarns) the poor crimp stability of bistructural textured yarns has led only to a few special textile applications.

4. Manufacture of Tow and Staple Fibers

4.1. Fiber Spinning

Spinning processes used in the production of tow and staple fibers can be divided into three major groups which are listed below in order of their commercial importance:

1) Melt spinning (conventional, compact, and continuous one-step processes)
2) Wet spinning
3) Dry spinning

The spun filaments are combined to form a tow, which is drawn, washed, heat-set, dried, crimped, and packaged. Staple fibers are obtained by cutting the tow into defined lengths.

4.1.1. Melt Spinning

4.1.1.1. Conventional Process

The basic principles of melt spinning are described in Section 2.1.3. Polyesters, polyamides, and polyolefins are currently the most important melt-spinnable polymers.

The molten polymer can be pumped directly from a polycondensation unit to the spinning unit (direct spinning). Alternatively, the polymer granulate is dried and/or conditioned, melted in a suitable screw extruder, and conveyed to the spinning unit [125]. Since a spinning unit generally consists of several identical spinning positions, the polymer is transported to the spin beam along paths of equal length by means of a distributor. The spin beam (Fig. 63) is connected to the spin pump (Fig. 64) and also accepts the spin packs (Fig. 65) by either top or bottom loading.

To achieve a uniform temperature throughout the entire spinning system, it should be heated with condensing diphyl (a eutectic mixture of diphenyl and diphenyl oxide, boiling range 256 – 258 °C at standard pressure) as heat-transfer medium.

The spin pump conveys a precisely measured volume of melt to the spin pack where it is distributed and filtered. Pressures may reach 20 MPa. The melt stream finally reaches the spinneret plate and is extruded through a multiplicity of holes [126] (Fig. 66). The hole capillary may display various profiles which shape the emerging melt stream and the resulting filament (Fig. 67).

After emerging from the capillary, the melt stream is cooled by heat exchange with the surroundings and solidifies to form a filament. Conditioned air is usually used as a cooling medium and is blown through the bundle of filaments. The air impinges on the filaments with a laminar flow at a defined velocity [127]. If circular or rectangular spinnerets are used, the necessary amount of air is blown across the filament bundle by means of a quenching shaft. In the case of annularly arranged holes or annular spinnerets, central quenching is used, in which air is blown either outward or inward from a tubular distributor and thus flows radially past the filaments (Fig. 68). Central quenching systems can handle a much larger number of holes than air shafts and, hence, increase polymer productivity per spinneret. They are thus more economical and, in addition, produce yarn of excellent quality [17]. Spinneret plates with a hole density of ca. 25 holes per square centimeter and a total of ca. 7000 holes can be used. Throughputs per spinning position of 240 kg/h and machine capacities up to 180 t/d can thus be attained. In contrast, the maximum possible number of holes in rectangular spinnerets is ca. 3000, and in circular spinnerets with cross-flow quenching systems ca. 700.

The extruded, solidifying filaments are drawn off by an external force and, depending on the polymer and the fineness, attain their final shape in a zone 3 – 200 cm below the spinneret. The bundle of filaments is then gathered together, redirected, and combined with bundles from other spinning positions to form a tow.

Spin finish is applied to the filaments prior to gathering by means of either a static system

Figure 63. Spin beam for fiber production
Courtesy of Inventa-Fischer AG, Domat/EMS, Switzerland,

(e.g., slot finishing) or a dynamic system (e.g., roller finishing). The spin finish normally consists of a mixture containing demineralized water and 0.1 – 5 % of a lubricant. In both cases the spin finish is applied by the finish applicator to obtain good tow cohesion, satisfactory electrostatic behavior, and the desired degree of fiber-to-fiber and/or fiber-to-metal friction. The tow then reaches the take-off unit which usually comprises four to six electrically driven godets (Fig. 69). The tow, which may be as large as 20 – 100 ktex ($\triangleq 2 \times 10^5 - 1 \times 10^6$ dtex) and moves at a speed of 8 – 33 m/s, finally reaches the delivery unit (also shown in Fig. 69). Here, the tow is usually picked up by so-called sunflower wheels, slightly undulated, and deposited in a container known as a spin can. The spin cans traverse below the delivery unit to ensure a uniform tow distribution (Fig. 70. They normally hold 500 – 8000 kg of tow.

Attempts have been made to replace this system by one in which the relatively high transverse tow velocity is reduced by forcing a rotary motion on it [129], [130]. However, these attempts failed due to economic reasons or damage to the tow.

Melt-spinning plants similar to the one described above usually occupy several floors (Fig. 71).

4.1.1.2. Compact Process

A compact, one-step process has been developed for the production of polyolefin fibers in which spinning is followed immediately by drawing [131]. In some cases this technology can also be applied to polyamides. The reason for this development is that polyolefins are best dyed with pigments in a melt. Since a broad range of colors is available, relatively small units are required with rapid changeover facilities.

Compact units have been designed which consist of a melt extruder, mixing devices for colored pigments, and a spin beam with 4 – 16 spinning positions. Spinnerets may have up to 80 000 holes. Extruded filaments are cooled by intense air blowing immediately below the spinneret. Throughputs of ca. 100 kg/h per position are attained at take-off speeds of 0.2 – 0.5 m/s. After being finished, the filament bundles are gathered, redirected, and fed immediately into a drawing zone. The speed of drawing is ca. 2.5 m/s. After drawing the tow is annealed, crimped, and, if necessary, heat-set. It is then cut into defined lengths and packed in a baling press. A 16-position machine operating in a fineness range of 1 – 3 dtex produces tow at a rate of ca. 15 t/d, the rate is higher for coarser fibers. Such a machine has a maximum height of 5.5 m and occupies a floor area of 35 × 6 m (Fig 72).

Figure 71. Conventional spinning plant for polyester staple fiber production

4.1.1.3. Continuous One-Step Process

The continuous one-step process [132], [133] was developed as a result of the lower speeds (< 16 m/s) used in conventional spinning and integrates drawing, annealing, crimping, heat-setting, and cutting. This process is primarily used for manufacturing polyolefin fibers but in special cases can also be applied to other melt-spinnable polymers such as polyester and polyamide.

Rectangular spinnerets are used for spinning, and four spinning positions arecombined into a draw-texturing unit. The delivery speed of the drawing and stabilizing step is 33 – 42 m/s at a fineness of 30 000 – 40 000 dtex. The multifilament tow is then crimped by a hot air-jet texturing system (cf. Section 3.3.3) and subsequently deposited on a heat-setting conveyor belt. A specially developed cutter, based on the principle of rapid cutting (see Section 4.2.5) divides the textured filament tow into staple fibers of the desired length.

An installation of this type has a height of ca. 5.4 m and is ca. 4 m wide and 18 – 30 m long, depending on the length of the heat setting oven; it can produce staple fibers at a rate of 8 – 10 t/d (Fig 73).

Figure 73. Flow diagram of a high-speed one-step process for continuous staple fiber production
a) Spinning; b) Drawing; c) Crimping; d) Heat setting; e) Cutting

4.1.2. Wet Spinning

The basic principles of wet spinning are described in Section 2.1.4.2, and the production of continuous filaments by this method is decribed in Section 3.2.2. If staple fibers are desired, the as-spun filaments produced by compact or combination spinnerets (Figs. 74 and 75) are gathered into a tow in, or on leaving, the spin bath. A typical spinning machine is shown in Figure 76. Spinning positions may be arranged on one or both sides. Spun filaments are drawn off at relatively low speed, but this is offset by using a very large number of spinneret holes.

In the continuous processes predominantly used today, the tow is guided directly to a drawing unit for further processing (cf. Section 4.2). Wet-spinning lines produce up to 90 t of polyacrylonitrile (PAC) tow per day (total fineness = 770 dtex) at a rate of 1.3 m/s. However, PAC fibers are also produced by the more economical melt-spinning process [134].

4.1.3. Dry Spinning

The basic principles of dry spinning are described in Section 2.1.4.1 and the production of continuous filaments by this method is described in Section 3.2.1. In the production of staple fibers, the tow leaving the spinning shaft is first guided over a finish applicator, then redirected and combined with the tow from other spinning positions. It is then taken off by driven rollers and deposited in spin cans. A dry-spinning unit for the production of staple fibers is illustrated schematically in Figure 77. Production rates range from 3 – 8 m/s.

4.2. Posttreatment of Tow and Staple Fibers

The properties of spun fibers do not meet the requirements for their final application. Strength is low, elongation and shrinkage are too high, and further processibility and blendability with natural fibers are not assured. As described for the one-step processes (Sections 4.1.1.2 and 4.1.1.3) and the wet-spinning process (Section 4.1.2),

Figure 74. Spinnerets used in the wet spinning of staple fibers

staple fibers must be converted to useful fibers by a suitable sequence of processing steps which include drawing, washing, heat-setting, drying, crimping, cutting, and packaging. These processes are carried out on fiber band production lines which can handle a large number of tows and may be up to 150 m long. The multiple tows are fed into the line and are processed simultaneously. Four widely used examples of such lines are illustrated in Figure 78. Lines produce 200 t of staple fibers per day and have a tractive power of 18 t, a production speed of 5 m/s and can handle a total drawn tow of 6×10^6 dtex [135].

4.2.1. Drawing of Tow

In the case of fibers produced by melt or dry spinning, the spin cans containing the as-spun fiber tow are placed in a can creel. As shown in Figure 79, the tow from these cans is plied and conveyed as a band to the drawing unit of the production line.

Prior to being drawn, the fiber band passes through an immersion bath filled with fluid to adjust its frictional properties and obtain a uniform temperature (Fig. 80A). The fluid consists of demineralized water and a lubricant. Drawing is performed between two or three sets of rollers and is referred to as one- or two-step drawing, respectively [136]. Drawing itself is always divided into two fields: the first comprising the range of draw up to the natural draw ratio and the second comprising the region beyond this ratio. The most common types of drawing used commercially are summarized in Figure 80.

Temperature control, the position of the draw point, and the type of draw used depend on the polymer and the production process and are proprietary know-how of the manufacturer. A suitable draw ratio must also be chosen to obtain a desired type of fiber from a specific polymer. Particular care must be taken not to leave any undrawn sections in the filament, which would result in uneven dyeing. Important factors in this respect are the density (decitex per centimeter) of the tow on the rolls, the uniformity of temperature control in the rollers and baths, modification of the frictional behavior of fibers by finish application, the drawing speed, the position of the draw point, and last but not least, maintainenance of constant operating parameters [1], [61], [84]. Today high-capacity polyester fiber lines (100 – 200 t/d) are equiped with a two-step pro-

Figure 78. Production line for polyester staple fibers
A) Can creel; B) Drawing and heat setting; C) Crimping and drying; D) Cutting and baling

cess with a immersion draw chest as the first stage.

The draw rollers are water- or vapor-heated and have a diameter up to 45 cm. The draw roller units are cantilevered and up to 1.8 m long, they can process more than 200 t of fiber per day. Draw ratios range from 1 : 2 to 1 : 6 and draw fineness is up to 600 ktex. The draw fibers leave the drawing zone at speeds up to 6 m/s. The drawing units must be able to withstand drawing forces up to 210 kN. A typical drawing unit is shown in Figure 81.

In the case of fibers produced by wet spinning, the multifilaments extruded from a large number of spinnerets are gathered to form a partial tow and washed prior to drawing. Multistep or continuous drawing is usually carried out in hot water which contains a small amount of solvent. The total draw ratio can be as high as 1 : 10.

4.2.2. Washing and Finishing

Washing. Fibers contain various components which must be removed by washing. Wet-spun fibers, for example, contain reaction products, and melt-spun fibers of nylon 6 may contain monomeric caprolactam. Washing can take place at various points along the fiber band production line: during or after drawing, after heat-setting, crimping (tow), or after cutting (flock). The following devices can be used to wash the tow or flock: dip tanks (tow), screen drums (tow/flock), and screen belts (flock).

Washing fluid (water) is circulated in the bath, and its volume, temperature, chemical composition, and concentration are controlled.

Figure 79. Production line showing the fiber band
Courtesy of Fleissner, Egelsbach, Germany

Finishing. The fiber surface must be provided with an appropriate finish to ensure suitable running properties during production and subsequent processing. In a fiber production line, the finish is applied by immersing the tow in an immersion bath at the head of the line which is filled with finish consisting of special lubrication oils (Fig. 82).

Alternatively, finish can be applied before the crimper using kiss rollers (Fig. 82D), into the crimper or after the crimper, or before the cutter by using a spraying unit (Fig. 82B and C). Finishes are applied with minimum loss, which means that little or no rinsing is required between process steps; this eliminates recovery costs and minimizes pollution of the environment.

4.2.3. Drying and Heat-Setting

Fibers are dried primarily to remove water and to obtain a commercially acceptable weight. However, heat-setting begins if drying is performed at high temperature; this considerably improves the fine structure of fibers (especially that of cellulose or wet-spun fibers). On the other hand, polyester fibers with stress-elongation character similar to that of cotton are dried at very low temperature ($< 90\,^{\circ}C$) to prevent changes in fiber structure; this represents pure drying. If the drying temperature were increased in this case, the fibers would be heat-set and thus lose their typical cotton-like properties. Drying and heat-setting can be carried out at constant length or with free or limited shrinkage.

After being drawn, cotton-like polyester fibers are heat-set at constant length on calenders (Fig. 83).

Calender rollers are heated with a suitable heat transfer oil and their surface temperature is brought up to $230\,^{\circ}C$. The tow is run over the requisite number of rollers, with appropriate contact times.

Heat-setting with free shrinkage is usually carried out in a plate belt dryer (Fig. 84A) or a screen drum dryer (Fig. 84B). Here, the material is deposited in meandering loops or in the form of flocks at the entrance to the dryer – setter and is transported through the system. The material is dried and heat-set by circulating a stream of heated gas, usually air. In addition to transfer of heat to the fiber material by means of contact or convection, radiation may also be used.

a) Immersion bath; b) Feed rollers; c) Draw rollers; d) Heat-setting rollers; e) Steam channel; f) Hot-water bath

4.2.4. Crimping

Texturing in staple fiber production lines is mainly performed with stuffer box crimpers. They are constructed in widths of 20 – 660 mm, can process 3 – 10 ktex of tow per centimeter of width, and operate at a speed of up to 7 m/s. The machines must be built with high precision and must be extremely sturdy. A crimping unit used in staple fiber production lines is shown schematically in Figure 85.

For defect-free processing of tow the material must be fed into the crimper homogeneously. To reduce the working widths of the tow bands from the preceding stage (drawing/heat setting) to the width of the crimper, they are folded with the aid of concave rolls or tow plyers. A dancing roll or a measurement unit is used to obtain uniform, constant tow band tension. Uniform temperature throughout the tow is provided by a steam or vapor zone which precedes the crimper and also affects the modulus of elasticity of the fiber and thus crimp formation.

In the crimper, the material is transported over temperature-controlled rollers, pushed against the plug of material that is forming, and thus forced to buckle (cf. Section 2.3.2.2). Crimp formation is determined by material properties (modulus of elasticity, diameter, friction), the geometry of the stuffer box, and the pressure selected in the box. Steam is often injected into

Figure 81. Drawing unit
Courtesy of Fleissner, Egelsbach, Germany

Figure 82. Finishing units for staple fibers
A) Immersion bath; B,C) Spraying units; D,E) Finishing units with kiss rollers

the box to set the texture. A crimper is shown in Figure 86.

4.2.5. Cutting

The continuous tow produced on the staple fiber production line is finally cut by mechanical cutters. For short fibers, the tow is cut into lengths of 6 – 18 mm. Staple lengths of 30 – 45 mm are suitable for processing in equipment designed to handle cotton; lengths of 60 – 150 mm can be processed in equipment designed to handle wool or wool blends.

In older, obsolete cutters, the tow moved over vertically running, slotted wheels and was cut between the slots by rotating sets of blades. Different types of cutters are now used, however.

Figure 83. Heat-setting calender

A) Plate belt dryer; B) Screen drum dryer
Cross sections of the dryers are shown on the right.

Figure 85. Crimping unit for staple fibers
a) Tow plyer; b) Dancing roller; c) Steam channel; d) Stuffer box

The LUMMUS system is capable of cutting tow at up to 600 ktex at a rate of 5 m/s. The material is wrapped around a rotating, horizontal ring of blades and pressed against the cutting edge of the blades by a pressure roll (Fig. 87).

Figure 86. Jumbo Crimper
Courtesy of Fleissner, Egelsbach, Germany

Figure 87. Cutter operating by the LUMMUS principle
a) Pressure disk; b) Tow; c) Cut staple fiber; d) Knife blade; e) Feed rollers

In a high-performance cutting system, the tow is drawn between a rotating cutter head and an inclined, free-running pressure disk positioned above it. The narrowing gap between the pressure disk and the cutter head builds up sufficient pressure in the tow to push the material through the blades (Fig. 88). This cutter can operate at high cutting speeds, and 10-ktex tows can be cut at 83 m/s.

In a third type of cutter, a continuous tow is cut by blades which are arranged in a pattern similar to the thread of a screw. The parallel arrangement of the fibers is thereby retained and the cut fibers therefore form a band. In contrast to the other cutting methods, natural fibers in the form of slivers can be blended with the staple fibers in a second step (converter process).

4.2.6. Packaging

Staple fibers are compressed into rectangular bales weighing up to 500 kg with material densities of > 0.5 g/cm^3. Usually, the fibers are transported pneumatically from the cutters to a prepress for preliminary compacting and are then brought to balesize in a main press. In the press, the material is wrapped in plastic sheeting and tied with metal or plastic straps.

Continuous tow is folded, deposited in boxes, and compacted with press rams. It can also be packed in bales if the tow is first folded and compacted in suitable containers.

5. Manufacture of Monofilaments

Monofilaments with diameters of ca. 0.06 – 2 mm have a wide range of applications, particularly in industry [137]. Monofilaments can only be produced from thermoplastic, melt-spinnable polymers such as polyamides [138], polyesters [137], polypropylene, polyethylene, and poly(vinyl chloride). Polymers that can only be spun by wet spinning (e.g., polyacrylonitrile) are not suitable for the manufacture of monofilaments. Strict requirements are placed on the properties of monofilaments, especially on the constancy of diameter, shrinkage, and strength. Specially optimized units have been developed which provide the required narrow tolerances and, at the same time, the most economical method of monofilament production [139]. Modern, industrial production of monofilaments is carried out in one step in which spinning, drawing, posttreatment, and winding are combined into a continuous process. A monofilament production plant is shown schematically

in Figure 89. Figure 90 shows a monofilament winding machine.

The polymer granulate is melted in an extruder; the melt is then filtered, fed into the spin nozzle and pressed through spinnerets. Additives such as lubricants or stabilizers can be added to the granulate or fed as a side stream into the extruder or into the melt line leaving the extruder. The additives are then distributed homogeneously in the melt with the aid of mixing devices.

Depending on the polymer and the diameter of the monofilament, up to 200 – 300 monofilaments can be spun simultaneously at each spinning position and posttreated in the form of a yarn warp. The melt pressure and the temperature of the monofilament spin heads must be kept constant within narrow limits to ensure that the simultaneously spun monofilaments are of consistent quality. The fluid melt monofilaments are spun into a water bath and drawn off continuously as a yarn warp over guide rolls. They are fed into drawing units equipped with three to seven draw rolls and hot steam or hot air channels.

Figure 90. Monofilament winding machine

Drawing temperature and draw ratio depend on the polymer used to produce the monofilaments and on the desired properties of the end product. Drawing can be followed by heat-setting and/or relaxing before the monofilaments are individually wound on flanged, conical, or biconical bobbins at a speed of 2 – 3.3 m/s. If necessary, a finish oil can be applied prior to winding. Computer-controlled winders with loss-free, fully automatic bobbin changers and up to 64 winding positions are available.

6. Process Technologies for Spunbonded Nonwovens

Nonwovens are classically produced by carding staple fibers (→ Nonwoven Fabrics). Spunbonded nonwovens, however, are made from continuous filaments in a one-step procedure; investment and production costs are thus lower. Thermoplastic polymers such as polypropylene, polyethylene, polyamides, or polyesters are melt spun through special spinnerets to form continuous filaments which are drawn by means of air streams and directly deposited as a random web on a moving collection screen belt. Finally, the filaments are bonded together by heat, chemical, or other entangling techniques, e.g., needle punching or hydroentanglement.

Several different process technologies are available for the industrial production of spunbonded nonwovens. They differ as to whether the filament bundles are spun from circular spinnerets or from rectangular spinnerets like a filament curtain. They also differ with regard to the production of air streams (over- or underpressure), their guidance and generally in depositing the filaments on the collecting belt (web formation).

A typical spunbond process [106] is illustrated in Figure 91. Spinnable thermoplastic polymer chips from a silo are melted in an extruder, into which colored pigments and other additives can be injected. The polymer is prefiltered through a melt filter (continuous type) and fed to the spinning beam. The spinning system is vapor-heated with a mixture of diphenyl and diphenyl oxide and ensures a constant temperature profile across the full width of spinneret. A spin pump forces the melt through the melt distribution line to the spinneret which contains several thousand capillary holes. Hole number, size (0.3 – 0.8 mm), and l/d ratio (1 – 6) mainly depend on the polymer properties, filament fineness, and required capacity.

The liquid filaments emerge from the spinneret, are cooled to room temperature with conditioned air, and enter into the aerodynamic draw-off system. To achieve a high tensile strength it is important that the drawing force caused by friction between air and filament surface is applied near the glass transition point. The drawing forces needed for high filament speeds are generated by the high velocities of the air (up to 16000 m/min) that is sucked in through the drawing slot. Depending on the polymer, filament speeds of, e.g., up to 6000 m/min for polyester and up to 4000 m/min for polypropylene are reached. The air – filament stream is directed downward into the web formation section, and the filaments are deposited on the moving screen belt. The filaments are distributed in a random and entangled manner by controlled turbulence and turbulent vortices in the air stream. As the web-formation chamber is directly connected to the drawing part and this space is fully protected, no disturbance by ambient air or other surrounding effects can take place. This feature minimizes edge trimming requirements and results in economical use of polymer. Underneath the conveyor belt the air is sucked off and recycled to the spinning section. Under predetermined spinning conditions, the fabric weight can be adjusted by varying the speed of the moving screen belt.

For boosting the productivity additionally one or more spinning beams can be added or a melt-blown system can be installed between two beams. This permits the production of spunbond/meltblown/spunbond (SMS). The power consumption of this suction process is relatively low compared with the process where the drawoff system operates with compressed air.

The process permits the production of webs with fabric weight of 8 to 300 g/m^2, widths between 0.6 and 4.6 m, and filament fineness ranging from 0.6 to 6 dtex.

7. Economic Aspects [145–147]

Since the mid 1970s, excess production capacities have resulted in fierce international compe-

tition among the producers of man-made fibers, particularly in industrialized Western countries. Later the most strongly growing market for man-made fiber was in Asian Countries. The economics and thus the competitiveness of a man-made fiber enterprise are affected to a high degree by the total capacity of its fiber and filament plants [2], by the size of the individual production lines, and by the technologies used.

Until the early 1970s, for example, the polymer required for the production of polyester fiber was made primarily in batchwise or continuous polycondensation plants with capacities of 30 – 60 t/d; dried granulate, as a rule, was thus the starting material used for spinning staple fibers and filament yarns. The profitability of a polyester plant increases considerably with increasing output capacity of a production line [17], [85], [142]. A particularly dramatic reduction in manufacturing costs can be achieved in continuous installations by omitting the granulate step and employing direct spinning in which the fibers are spun directly from the melt. Investment costs for buildings and equipment are lower, and energy consumption is reduced because granulate no longer has to be produced, dried, and remelted. As a result, almost all polyester fiber plants built today are continuous production lines which employ direct spinning; production capacities are 100 – 200 t/d in one line.

Figure 92. Dependence of investment costs on number of spinning positions and number of holes per spinneret
Figures are based on a melt-spinning unit with central quenching and a production capacity of 45 t/d

Investment and manufacturing costs of polyester staple fibers are affected to a high degree by the output of the spinning positions and the capacity of the drawing units. Figure 92 shows that investment costs of a staple fiber

Figure 93. Comparison of investment and production costs for fiber production lines in relation to their capacity

spinning plant can be halved by doubling the 1215 spinneret holes per spinning position and halving the number of spinning positions. Figure 93 demonstrates that manufacturing costs in the drawing unit can be more than halved if the installation has a capacity of 90 t/d instead of 30 t/d.

Efforts to improve competitiveness in the area of filament yarns have focused on reducing investment costs by combining multistep, discontinuous processes into a single, continuous process. One-step processing also reduces manufacturing costs by cutting down personnel requirements. However, modern one-step processes not only provide cost advantages, but generally result in an improvement in the quality of filament yarns.

Studies of the most important factors affecting the manufacturing costs involved in draw texturing show that an integrated, one-step, spin-draw texturing process is more economical than conventional draw texturing only if the texturing speed can be increased above 67 m/s [143].

In processes used to produce filament yarns (e.g., spinning, high-speed spinning, spin drawing, draw texturing), the number of yarn ends per spinning or drawing position has a considerable influence on the manufacturing cost of the end product. In draw texturing used to produce BCF yarns, cost advantages are obtained if finenesses up to ca. 1000 dtex are processed on a four-end machine instead of a two-end machine [144]. The break-even point is calculated to be a fineness of 1200 dtex.

Fierce international competition in the production of synthetic fibers and the construction of synthetic fiber plants is forcing the man-made fiber industry and engineering companies to develop new, lower cost, better quality technologies. Only the replacement of out-of-date, unprofitable production facilities by new, highproductivity technologies can assure the long-term profitability and competitiveness of an enterprise.

The following is a list of specific abbreviations used in this article.

BCF	bulked continuous filament
CPVC	postchlorinated poly(vinyl chloride)
DMA	dimethylacetamide
DMF	dimethylformamide
DMSO	dimethyl sulfoxide
DMT	dimethyl terephthalate
FOY	fully oriented yarn
HALS	hindered amine light stabilizer
HDPE	high-density polyethylene
HE	highly elastic
HOY	highly oriented yarn
HT	high temperature
LDPE	low-density polyethylene
LOI	limiting oxygen index
LOY	low-oriented yarn
MDI	methyl diisocyanate
MFI	melt flow index
M_rD	molecular mass distribution
PAC	polyacrylonitrile
PACM	bis(4-aminocyclohexyl)methane
PBT	poly(butylene terephthalate) = poly(tetramethylene terephthalate)
PDCT	poly(1,4-dimethylenecyclohexane terephthalate)
PETP	poly(ethylene terephthalate)
POY	partially oriented yarn
PP	polypropylene
PTFE	poly(tetrafluoroethylene)
PUR	polyurethane
PVA	poly(vinyl alcohol)

PVC	poly(vinyl chloride)
PVDC	poly(vinylidene chloride)
TDI	tolyl, tolylene, or toluene diisocyanate
TMA	thermomechanical analysis
TPA	terephthalic acid
UHMM	ultrahigh molecular mass
UHMMPE	ultrahigh molecular mass polyethylene

1. Polyamide Fibers

This chapter deals predominantly with linear polyamide fibers derived from aliphatic monomers, all of the generic class called *nylon.* Linear, aliphatic polyamides are conveniently divided into two groups: those made from aminocarboxylic acids and those made from diamine – dicarboxylic acids. These are characterized by the number of carbon atoms in the monomeric starting material. For example, nylon 11 is the polycondensate of 11-aminoundecanoic acid [$H_2N(CH_2)_{10}COOH$]. Nylon 610 is the polycondensate of 1,6-diaminohexane [$H_2N(CH_2)_6NH_2$] and sebacic acid [$HOOC(CH_2)_8$ COOH]. Fibers of aromatic polyamides in which the amide linkages attach directly to two aromatic rings are called aramids, and are covered under → High-Performance Fibers. World production of nylon fiber reached 3.4×10^6 t/a in 1985 and is expected to grow slowly. The 45-year history of the beginning and growth of nylon has been reviewed [7].

1.1. Properties

Nylon fibers are superior to all natural and regenerated fibers with respect to high tenacity and elongation, abrasion resistance, and insensitivity to rotting and moth attack. By heat treatment, fabrics of nylon fiber can be set into stable shapes through formation of additional hydrogen bonds. The highly polar nature of carbonamide groups also results in swelling of nylon fibers in water or in polar solvents, and permits simple dyeing processes with disperse, acid, and metallized dyes. Nylon fibers absorb moisture and swell longitudinally. This limits "outdoor" use because of poor dimensional stability.

Other general properties of nylon are as follows:

Shrinkage: dependent on conditions; 1 – 15 % when setting in water or hot air

Abrasion resistance: outstanding; especially suitable for textile floor coverings

Electrostatic charge: high at low relative humidity; reduced significantly in antistatic fibers (addition of carbon black or polyglycol ether compounds)

Solubility: at room temperature in concentrated inorganic acids, *m*-cresol, *o*-chlorophenol, and phenol – alcohol mixtures; at the boil in benzyl alcohol and phenylethyl alcohol

Dyeability: with acid, metal-complex, disperse, and reactive dyes; special types with basic dyes

Stability:

Light stability: highly dependent on pigmentation and presence or absence of stabilizers

Thermal oxidation: yellowing and molecular degradation reduced by stabilizers (Cu^+ or antioxidants)

Weathering: relatively poor outdoor life, especially with fine deniers

Dilute acid: adequate resistance

Dilute alkali: good resistance

Biological stability: good to very good resistance against decay-producing bacteria, mold fungi, and moth larvae

Shape stability: good crease resistance with dry materials. On absorbing water, nylon fibers swell in the direction of the fiber axis. The lengthening must be considered in the manufacture of clothing, especially with nylon 6 and nylon 66. With felts for floor coverings, dimensional stability is improved by blending with nonswelling fibers such as polypropylene.

Physical properties of four nylon fibers are given in Table 1.

Table 1. Physical properties of some nylon fibers

Property	Nylon 6	Nylon 66	Nylon 11	PACM-12∗

1.2. Polyamides for Synthetic Fibers

The high molecular mass, linear polyamides that are useful for synthetic fibers contain mainly methylene groups between the carbonamide groups. They comprise those compositions that can be melted and spun into filaments without decomposing.

The introduction of cyclic segments into an aliphatic polyamide chain generally stiffens the chain and raises the melting point (Table 2). The effect is most pronounced when the ring structure is aromatic and symmetrical, and when the amide group is connected directly to an aromatic ring. Connection of two aromatic rings to the amide group defines the aramid class of polyamides, which usually degrade without melting and cannot be melt-spun. Melt temperature is also strongly affected by ring symmetry, as seen in the 90 °C difference in melting points of the meta and para isomers of the two xylene diamines.

Introduction of C-alkyl side chains in nylons disrupts molecular order and leads to both a reduction in melt temperature and increased solubility in organic solvents. The influence of N-alkyl substituents is even greater, because they eliminate the possibility of hydrogen bonding between polyamide molecules. The polyamide of piperazine and adipic acid, which melts at 185 °C, is of scientific interest because the effect of the missing hydrogen bonds is largely compensated for by chain stiffening through the piperazine radical.

The effect of C-methyl and N-methyl groups on the melting temperature of nylons made from adipic acid and a diamine is as follows:

$H_2N-(CH_2)_4-NH_2$	251 °C
$H_2N-(CH_2)_2-CH(CH_3)-(CH_2)_3-NH_2$	180 °C
$HN(CH_3)-(CH_2)_6-NH_2$	145 °C
$HN(CH_3)-(CH_2)_6-NH(CH_3)$	− 75 °C

Substitution of oxygen or sulfur for a methylene group in aliphatic polyamides also results in a lower melting point. In the low molecular mass region, nylon melt temperatures increase significantly with increasing molecular mass. This effect, however, can be neglected at the high molecular masses necessary for fiber production. The strength of nylon fibers also increases with increased molecular mass, but melt spinning has technological limits because of the difficulty of handling very high melt viscosities.

The melting temperature of nylon decreases with increased ratio of methylene groups to carbonamide groups, and approaches the melting temperature of polyethylene (*mp* 130 – 150 °C, depending on molecular mass). Thus, nylon 22 melts at 145 °C. However, melting temperatures of the two types of nylon do not decrease uniformly, because nylons in the homologous series with an even number of methylene groups between carbonamide groups melt at higher temperatures than the adjacent nylons with an odd number of methylene groups (Tables 3 and 5). This is because the geometrical symmetry of the even-numbered configuration permits tighter chain packing and better hydrogen bonding. Wa-

12	179	1.3	2.7	100	

ter absorption and nylon density also decrease with increased number of methylene groups, i.e., as the molecule becomes more alkane-like (Table 3).

1.2.1. Aminocarboxylic Acid Type Polyamides

Nylons of the aminocarboxylic type can be prepared by the following methods:

1) polycondensation of ω-aminocarboxylic acids having more than five carbon atoms
2) hydrolytic polymerization of lactams having more than six ring members, and
3) anionic polymerization of lactams with exclusion of water.

Tables 1 and 3 list the most important *physical properties* of this type. Fibers are characterized by a high tenacity of 6 – 7 g/dtex and a break elongation of 20 – 30 %. An exception is nylon 4, with a tenacity of ca. 4 g/dtex.

Nylon 1 [*32010-01-8*]. Nylon 1 falls into this class by virtue of the linear connection of carbonamide groups; it is a polyamide based on its chemical structure [8]:
−CO−NH−CO−NH−CO−NH−.
However, derivatives prepared from monoisocyanates have no polyamide properties.

Nylon 2 [*25734-27-4*]. The polyamide from aminoacetic acid is really the first member of the series defined by the general formula $H[HN-(CH_2)_n-CO]_xOH$ ($n = 1$). So far, preparing nylon 2 with sufficiently high molecular mass for the production of fibers has not been possible. A high order of crystallization would be expected, and spinning would only be possible by a solvent spinning process. Filaments of nylon 2 could resemble natural silk very closely in physical properties.

High molecular mass nylon 2 derivatives alkylated on the α-carbon atom may be also viewed as polypeptides of α-aminocarboxylic acids and can be prepared by ionic polymerization of *N*-carboxylic acid anhydrides:

Polymerization can be initiated with a variety of catalysts such as alkali hydroxides and carbonates, phenols, and amines. Spinnable polymers have been obtained only from pure optical isomers, i.e., L- or D-aminocarboxylic acid

derivatives. The Japanese have produced semi-works quantities of polypeptide fibers based on L-glutamic ω-ester, which are reported to have unusual properties.

Nylon 3 [*25513-34-2*]. Nylon 3 would be expected to have good fiber properties, but no economically attractive route to its preparation has been found. It melts at 330 °C and should be spinnable to fibers from superheated aqueous solutions [9].

C-Alkyl derivatives of nylon 3 are of interest for fibers because of new syntheses of corresponding β-lactams [10].

Chlorocyanogen and sulfur trioxide react to form the easily accessible *N*-carbonylsulfamidic acid chloride. Under mild conditions, this reacts with olefins to form the β-lactam-*N*-sulfonyl chloride, which can be converted to the β-lactam through hydrolysis in a weakly acidic medium:

Because both the β-lactams and the corresponding polyamides generally decompose above 250 °C, these nylons are prepared preferably through anionic polymerization in solution, at temperatures of − 15 to 30 °C. For copolymerization, the β-lactams must have reasonably similar polymerization rates. Polymerizations are anhydrous with alkaline catalysts, e.g., alkali lactams or N-alkyl lactams. In contrast to melt-spun polyamides in which molecular masses of 15 000 to 25 000 are adequate for good fiber properties, molecular masses of > 200 000 are required for β-lactams, where fibers are made by solution spinning. Fibers with good textile properties and remarkedly good oxidative stability can be prepared from poly(β,β-dimethyl-β-propriolactam), spun from a ca. 15 % solution. Typical solvents are trifluoroethanol, phenol, and dimethyl sulfoxide.

Nylon 4 [*24938-56-5*]. The polycondensate of 4-aminobutyric acid is prepared by anionic polymerization of γ-butyrolactam in the presence of alkaline catalysts at < 60 °C.

The reaction is carried out in an inert hydrocarbon solvent, and conversion is ca. 80–85 %. Precipitated polymer must be washed thoroughly to remove residual monomer, traces of which accelerate decomposition of the polymer at the melting point. Nylon 4 can be melt-spun at 279–280 °C, but residence time in the melt must be short to avoid decomposition or reversion to γ-butyrolactam. Nylon 4 can also be spun from a 45 % formic acid solution, but lower tenacity is obtained. Because of its relatively high water absorption (9 % at 65 % R.H.), nylon 4 can be dyed easily, but it has relatively poor crease resistance. The fibers have not been significant economically, in part because of their poor temperature sensitivity in spinning [11].

Nylon 6 [*25038-54-4*]. While not ideal for optimum fiber properties, nylon 6 represents about half of the commercial production of nylon fibers and occupies a transitional position in this series. Whereas 4-aminobutyric and 5-aminovaleric acid proceed smoothly to the corresponding lactams on heating above melt temperature, 6-aminocaproic acid forms a temperature-dependent equilibrium condensate. At 250 °C, this consists of ca. 89 % linear polyamide, 8.5 % caprolactam, and 2.5 % larger ring amides. This equilibrium condensate is identical with the equilibrium polymer that results from hydrolytic polymerization of ε-caprolactam.

Problem-free continuous polymerization of caprolactam (→ Caprolactam) can be carried out in perpendicular flow-through tubes, with small additions of water, at 240–270 °C and atmospheric pressure. Batch polymerization in pressure autoclaves can also be carried out, which is a preferred technique for small production units or for polymer with special additives. Anhydrous caprolactam can also be polymerized with alkaline catalysts or cocatalysts, but this "fast polymerization" is not used in the manufacture of fibers. Excess caprolactam and higher ring amides must be removed from the equilibrium mixture before further processing to fibers. The equilibrium melt is extruded, solidified, cut to granules or flake, washed repeatedly with boiling water, and then vacuum dried. This can be done batchwise or continuously. Careful exclusion of oxygen is essential in all processing steps. Nylon 6 can also be polymerized and spun directly by passing the equilibrium polymer through a continuous, thin-film evaporator to remove impurities and then pumping it

directly to the spinning machine [11, pp. 121–134].

Because of its relatively low melting point and high water absorption, and the lack of a technically simple way to convert monomer to a continuously spinnable melt, nylon 6 is not the best aminocarboxylic acid type for producing synthetic fibers. The reason for its great importance and large production volume is economic. The high-purity caprolactam required for fiber production is made from favorably priced raw materials (benzene, cyclohexane, or phenol).

Nylon 7 [*25035-01-2*]. Nylon 7 is generally considered to be the optimum aminocarboxylic acid type polyamide for fibers. In both the condensation of 7-aminoheptanoic acid and the hydrolytic polymerization of enantholactam, yields of linear polymer exceed 99 %. This means that nylon 7 can be produced continuously in a technically simple polymerization-spinning process. Textile properties of nylon 7 fibers are superior to those of nylon 6 and, to a degree, those of nylon 66. Of particular interest, compared to nylon 6, are the 10 °C higher melting temperature and reduced water absorption. These two properties lead to important advantages, i.e., a considerably higher wet modulus and improved crease recovery (Table 4).

To date, no economically competitive route for production of the monomer has been reported. Small quantities of nylon 7 are produced in the former States of USSR. For this, 7-aminoheptanoic acid is reportedly prepared by telomerization of carbon tetrachloride and ethylene, via the intermediate 7-chloroheptenoic acid.

Nylon 8 [*25035-02-3*]. Nylon 8, which melts at 200 °C, is prepared by hydrolytic polymerization of caprolactam. The equilibrium polymerizate contains only traces of ring amide, so that fibers can be produced by using a continuous polymerization-spinning process. Because of the reduced number of carbonamide groups, water absorption is low, which provides relatively good wet strength and wet elasticity. However, raw materials for the synthesis of caprolactam are too expensive for this polymer to be attractive economically.

Nylon 11 [*25035-04-5*]. The synthesis of nylon 11 is based on a five-step process from castor oil to 11-aminoundecanoic acid. A 30–40 % aqueous dispersion of the acid can be polycondensed in three steps, and the nylon 11 formed can be isolated and melt-spun. Addition of phosphoric or phosphorus acid facilitates spinning by raising the melt viscosity and limiting side-chain growth. As expected from the longer hydrocarbon chain, nylon 11 shows hardly any sensitivity or dimensional change in the presence of moisture. The fibers are too expensive for general use and are restricted to a few special applications in luggage, ropes, transmission belts, and bristles.

Nylon 12 [*24937-16-4*]. Nylon 12 is prepared by hydrolytic polymerization of lauryl lactam, made by a four-step process from butadiene. The reaction to give polymer is essentially complete, so spun products can be prepared by using a continuous polymerization-spinning process. Because nylon 12 has good thermal stability, polymerization temperatures can be raised to 310–340 °C [13]. Except for a 10 °C lower melting point, fiber properties of nylon 12 closely correspond to those of nylon 11. These fibers are not made in large volume because of cost, and their use is restricted mainly to industrial specialty areas.

1.2.2. Diamine–Dicarboxylic Acid Type Polyamides

Nylons of this group are prepared for fiber use primarily by thermal polycondensation of equimolar amounts of diamines and dicarboxylic acids or their salts. Monomers that can undergo intramolecular condensation, like glutaric and succinic acids, are not suitable for thermal polycondensation. In commercial practice, aqueous solutions or suspensions of the salt are processed in batchwise or continuous operation. Polycondensation is induced initially by treatment of the concentrated salt under pressure to avoid loss of diamine, and then under vacuum to increase molecular mass to the degree required for fiber production.

This type of nylon can also be prepared from diamines and dicarboxylic acid dichlorides through interfacial polymerization. Some nylons, with melting temperatures in a range suit-

	sebacic	1010	194 – 203

able for melt spinning, 180 – 280 °C (Table 5), are obtained by combination of aliphatic diamines and dicarboxylic acids. However, only nylon 66 has any economic significance.

Nylon 46 [*24936-71-8*]. The fiber from 1,4-diaminobutane and adipic acid is claimed to have better high-temperature properties than nylon 66 [14]. Good strength retention and low shrinkage suggest industrial applications.

Nylon 66 [*32131-17-2*]. Because raw materials are favorably priced for producing both adipic acid (cyclohexane) and 1,6-diaminohexane (acrylonitrile, butadiene, and adipic acid), nylon 66 has outstanding economic importance in the production of synthetic fibers (→ Adipic Acid; → Cyclohexane).

For the production of fiber-grade polymer, a 50 – 60 % aqueous nylon salt solution is heated in a pressure autoclave, with careful exclusion of oxygen. The pressure is released slowly, and the

resultant low molecular mass polymer is heated under vacuum in the same vessel to increase molecular mass and melt viscosity to the level required for fiber spinning. Polycondensation can also be carried out continuously [15] and the resultant melt pumped directly to the spinning machine.

Nylon 610 [*9008-66-6*]. Nylon 610 is prepared under conditions similar to those for nylon 66. Because of low water absorption and high elasticity, nylon 610 is especially suitable for production of bristles. The cost of sebacic acid, produced from castor oil, is fairly high and limits the use of this polymer.

Nylons Containing Aliphatic or Aromatic Rings. There is currently no significant commercial production of linear polyamides containing aliphatic or aromatic ring structures. Many have been investigated for use in tires for improved flat spotting, for better carpet aesthetics, and for improved wrinkle resistance and tactile aesthetics in nylon apparel fabrics. Systematic studies have been reported on fibers or films using phenylenediamine, $C_6H_4(NH_2)_2$, and C_4 to C_{12} diacid chlorides [16], and on the relative effects of cyclohexylene and phenylene linkages in polyamide fibers prepared from C_6 to C_{12} aliphatic dicarboxylic acids [17].

One ring-containing nylon fiber, T-472 [*26403-85-0*], was marketed commercially in the early 1970s by Du Pont. It was based on bis(4-aminocyclohexyl)methane and dodecanoic acid.

The diamine is obtained by catalytic hydrogenation of 4,4′-diaminodiphenylmethane (made from aniline and formaldehyde), resulting in a mixture of cis, trans isomers. The mixture must be fractionally crystallized to yield the preferred 70 % trans, trans product [18]. This isomeric mixture is polycondensed with dodecanoic acid to yield a melt-spinnable polymer (*mp* 275 °C) and fibers with high tenacity and resilience, and low water sensitivity.

The luxury, silklike fabric made from T-472 fiber was marketed under the registered trade name Qiana. The product was withdrawn from the market in the early 1980s for economic reasons.

1.2.3. Copolyamides

Nylon copolymers are formed easily by polycondensation of monomer mixtures. Compared to the corresponding pure polyamides, they have lower melt temperatures and higher solubilities. In the case of copolyamides of 6-aminocaproic acid and 1,5-hexanediammonium adipate, the melt temperature minimum is ca. 160 °C at 60 wt % of the amino acid. The melting temperature of the copolyamides can be reduced still further through ternary monomer mixtures. Low-melting copolyamides are suitable, for example, for thermal bonding of needle felts and nonwoven fabrics. Copolyamides of ε-caprolactam and 11-aminoundecanoic acid are especially suitable for fishing lines because of good flexibility and increased transparency.

1.3. Special Requirements for Polyamides

The *purity* of all nylon starting materials is especially important because reactive impurities result in uncontrolled chain growth and can reduce the quality of the spun product, e.g., by increased yellowing tendency. Mechanical impurities must be removed carefully by filtration before polymerization. The polymer melt is also filtered to remove mechanical impurities and pigment agglomerates, by passing it through a bed of sand or powdered metal and fine screens, just before it is extruded in filament form. This is especially important in the production of fine-denier filaments in which coarse impurities can reduce quality and yield through filament breaks.

Because nylons are particularly sensitive to oxidation at elevated temperature, *oxygen* must be scrupulously excluded in both the polymerization and the spinning steps. The oxygen content of the inert gases used, primarily carbon dioxide and nitrogen, should be maintained below 0.001 %. In both the hydrolytic polymerization of lactams and the polycondensation of aminocarboxylic acids, an equilibrium exists whose position is influenced substantially by the water content of the polyamide melt:

$$\mathrm{H[HN{-}(CH_2)_n{-}CO]_aOH + H[HN{-}(CH_2)_n{-}CO]_bOH} \rightleftharpoons \mathrm{H[HN{-}(CH_2)_n{-}CO]_{a+b}OH + H_2O}$$

Water removal leads to an increase in average molecular mass; water addition reduces average molecular mass. The same is true for nylons of the diamine – dicarboxylic acid type. *Viscosity stabilizers* are added to the monomeric starting materials to control the degree of polymerization and prevent an undue increase in viscosity in remelt. Both monofunctional and bifunctional compounds are used to limit chain growth. Especially suitable for this purpose are primary and secondary aliphatic amines or diamines, aliphatic and aromatic carboxylic acids, and dicarboxylic acids. Examples are cyclohexylamine, 1,6-diaminohexane, acetic acid, benzoic acid, and adipic acid. Trifunctional compounds are undesirable because they lead to molecular branching.

Good *analytical control* of polymer quality is essential to good spinning continuity and high fiber quality for all synthetic polymers. A narrow molecular mass distribution is desirable. Broad distributions can result from improper design or improper operation of a continuous polymerizer for nylon, and this frequently leads to inferior fiber properties.

Molecular mass distribution

can be determined by using the ultracentrifuge [19], by turbidity titration, by fractional precipitation or partition between two liquids, or by chromatography. From the molecular mass distribution, molecular mass can be calculated as the number average (M_n) or the mass average (M_m). The ratio M_m/M_n is always greater than 1 and is a numerical measure of molecular nonuniformity. The absolute value of M_n can be determined cryoscopically, osmotically, or through end-group analysis; M_m can be determined by light scattering [20] or by the hypsometric distribution of macromolecules in ultracentrifugal sedimentation.

The simplest and most commonly used method for obtaining relative values of mass-average molecular mass (M_m) is measurement of solution viscosity [19, pp. 49 – 67] in a capillary viscometer at constant temperature, where

$\eta_{relative}$ = flow time of the solution divided by flow time of the solvent

and

$\eta_{specific} = 1/\eta_{relative}$

Suitable solvents are concentrated sulfuric acid, formic acid, and phenol. The specific solution viscosity, $\eta_{specfic}/c$, referred to the polyamide concentration in grams per 100 mL, is concentration dependent. Plotting viscosity as a function of decreasing concentration and extrapolating to zero yield the intrinsic viscosity, which is directly proportional to M_m. In the production of nylon fibers, sufficient control of the process can be achieved by routinely measuring and controlling the viscosity of a standard solution, e.g., 1 g/100 mL. The melt viscosity, of practical importance for melt spinning, can be determined in rotary, torsional viscometers and capillary viscometers, or by using the falling ball method. In measuring melt viscosity, oxygen and moisture must be rigorously excluded and temperature held constant. On melting, polyamides can change by amide ring formation, molecular mass increase, and degradation, so melt viscosity is likely to vary according to method and measuring conditions. In general, the melt viscosity of polyamides for melt spinning is ca. 50 – 500 Pa · s.

The *free amino and carboxyl end groups* of polyamides are determined by potentiometric or conductometric titration with dilute perchloric acid and alkali hydroxide solution, respectively. A solvent mixture of phenol, ethanol, and water is suitable for amino-group titration. A supersaturated polyamide solution, in benzyl alcohol or α-phenylethyl alcohol, is used for carboxyl end-group determination. This analytical procedure cannot be used for all polyamides.

Water analysis is carried out by heating the flake or fiber, and released water vapor is carried with dry nitrogen into Karl Fischer reagent. In this method, both the physically bound water and that formed by chemical reaction are determined.

Extractable materials in nylon 6, caprolactam, and higher ring amides can be determined by extracting the finely divided polymer for several hours in water or lower alcohols. However, in this relatively simple method, the high ring amides are not extracted completely. For quantitative determination and separation of ring amides, the polymer is dissolved in formic acid and the linear polyamide molecules are then precipitated by addition of methanol. Ring amides can be determined quantitatively in a methanol solution by using gel chromatography.

1.4. Modifying Additions

Nylons that absorb water and swell, such as nylons 6 and 66, can be dyed relatively easily with *disperse, acid, or metallized dyes*. The dye molecules migrate readily into the fiber structure. The dyeing of nylon fibers with acid dyes results from reaction with the amino end groups. The number of such reactive sites is influenced by M_n but can be modified by additives such as viscosity stabilizers. For example, carboxylic stabilizers will block amino groups and reduce affinity for acid dyes. The use of primary aliphatic amines or diamines provides additional basic sites and increases acid dyeability. Introduction of tertiary amine groups into the chain strongly increases absorption of acid dyes.

Nylons can be modified to accept *basic dyes* by introduction of strong acidic groups such as sulfonic acids, e.g., 5-sulfoisophthalic acid, in equimolar mixture with 1,6-diaminohexane [21]. Polycolor effects (graduated color depth, variable color and shades) can be achieved by dyeing fabrics of mixed nylon fibers with different dyeabilities in a single dye bath containing acid, basic, and disperse dyes.

Delustering is the practice of altering the optical properties of a fiber, usually by incorporation of a white pigment. This is most often done for textile uses. The most common delusterant is titanium dioxide [*13463-67-7*], added in amounts of 0.03 – 2 %, depending on the effect desired. Of the two forms of titanium dioxide available, the anatase variety is preferred for continuous-filament yarns because the harder rutile modification causes excessive abrasion and wear on guide surfaces and machine parts over which the yarn runs. The rutile form can be used with staple fibers in which guide wear potential is not so serious. Other pigments, such as clay, can also be used. Delustering can also be accomplished by surface roughening or by introducing voids into the filament.

Size distribution [22] of titantium dioxide pigments and pigment aggregates is generally 0.1 – 1.0 µm, with a frequency maximum in the region of optimum turbidity at 0.2 – 0.4 µm. However, commercial pigments also contain larger agglomerates, which must be broken down through wet grinding or separated from the aqueous dispersion by fractional sedimentation. Pigment agglomeration must be avoided in pigment addition to the monomer or to the polymer melt, because the particles result in filter plugging as well as weak sections in the filament. For continuous production of nylon flake or fiber, adding a pigment – polymer concentrate of 20 – 40 % titanium dioxide to the melt just before spinning is advantageous. This permits quick conversion to different degrees of delustering, but also imposes strict requirements on control and mixing.

The magnitude of pigment addition can be checked by ash determination or photometric titanium analysis. The uniformity of pigment distribution, as well as the number and size distribution of pigment agglomerates, can be analyzed by microscopic examination of thin fiber cross sections.

Aging and light protection must be provided for some nylons by addition of special additives [23]. Manganese(II) compounds, in amounts as low as 5×10^{-4} %, are especially effective for nylons 6 and 66. Titanium dioxide pigments, especially of the anatase type, reduce light resistance, and one variety of anatase TiO_2 is coated with manganese to offset this effect. Many manganese compounds, such as the acetate, sulfate, phosphate, polyphosphate, and glycerophosphate salts have been proposed. In selecting the type and amount of additive, undesirable side effects, such as yellowing of the filaments and extraction of the manganese(II) during dyeing or wet finishing, must be considered in addition to the light-protective ability desired. Use of a manganese salt with a reducing anion, such as manganese(II) hypophosphite, improves the whiteness of fibers. Addition of sodium phenylphosphinate, in combination with manganese(II) hypophosphite, substantially improves both whiteness and quality [24].

The *heat-aging resistance* of nylons must be improved for uses such as the tire cord. The thermal – oxidative degradation of nylon can be reduced considerably by adding antioxidants (0.1 – 1.0 %), such as substituted aromatic diamines, and their action can be increased by combining them with trialkyl phenyl phosphites. Textile nylon, for which yellowing cannot be tolerated, requires special phenolic antioxidants substituted with alkyl radicals in the positions ortho to the – OH group. Examples are the amine salts of 3,5-dialkyl-4-hydroxyphenylcarboxylic acids. Copper(I) salts, in amounts as

low as 5×10^{-4} % copper, are also effective. Many synergistically acting stabilizer mixtures are described in the literature, e.g., complex compounds of copper(I) iodide and hydrocarbon phosphines or phosphites are said to be especially effective.

Spin Dyeing and Optical Brightening. Inorganic and organic pigments for spin coloration of nylons must be stable under melt processing conditions and must give high colorfastness [25]. Pigment particle size should be less than 1 – 2 µm to avoid impairment of fiber strength, and agglomerates must be carefully milled or separated by sedimentation. Colored pigments are generally added to the starting monomer as aqueous dispersions. They may, however, be added to the melt as pigment – polymer concentrates [26]. This technique is desirable for short commercial runs but requires precise metering and good mixing.

Suitable additives for *spun-dyed nylon* are the yellow to red cadmium pigments, anhydrous iron oxide pigments, ultramarine, copper phthalocyanine, perylene, and quinacridone pigments. Because nylon melts generally have a strong reducing action, perylene pigments can be reduced on the surface with a significant change in color. However, reoxidation often occurs in air shortly after extrusion of the filament. Some azo and anthraquinone dyes are also soluble in nylon melts and are sufficiently stable for spin dyeing.

Dyeing of nylon flake in aqueous baths, before spinning, is an economical way to produce a large range of colors from one flake type. However, the resulting colors do not have the outstanding fastness of pigment-spun fibers.

Black nylon fibers are obtained by using carbon black pigments with an average particle size of 10 – 30 µm. Carbon black pigment in too high a concentration can block carboxyl groups, reduce the degree of polymerization, and impair flow behavior of the melt.

Optical brighteners are frequently used to improve aesthetics of textile fibers, especially to hide the effects of soiling. The more stable brighteners are added to the monomeric starting material, the less stable ones, such as the coumarin type, are injected into the melt.

1.5. Technology of Melt Spinning

1.5.1. Melt Spinning of Nylon

All commercially significant nylons are melt-spun at temperatures up to ca. 300 °C [27]. Processes may be continuous from monomer to spun fiber, or they can be staged. When a variety of small-volume products is required, producing nylon flake and remelting it for the spinning process are economically advantageous. This is especially true for nylon 6, which must be washed to extract polycondensation byproducts.

In modern plants, flake is usually stored in large hoppers and then transported pneumatically or in smaller hoppers to the spinning area. Prior to spinning, the flake must be conditioned to proper moisture content because this can have a strong effect on melt viscosity. Great care is taken to store and transport flake with exclusion of moisture. Also, before being delivered to the melt unit, fines and excessively large cuts, as well as contaminating metal particles, are removed.

Nylon flake is commonly melted by using screw extruders or, in the older process, heated grids or grates. In either case, oxygen must be rigorously excluded. Spinning temperature depends mainly on the thermal stability and melt viscosity of the nylon. With nylon 6 and nylon 66, temperatures are usually kept at 280 – 290 °C. After leaving the melt unit, polymer is delivered to a metering pump and then to a spin pack. The pack contains filter media, passages for distributing polymer within the pack, and a spinneret. The filter section serves to remove mechanical impurities and to provide high shear for the melt. In a typical filter section, the molten polymer passes through layers of either powdered metal or fine sand, then through layers of very fine mesh screen, and finally through a photoetched plate before reaching the spinneret.

The spinneret is a metal plate, usually 6 – 10 mm thick, filled with holes, each hole forming one filament. Filaments from round spinneret holes have circular cross sections. The cross section can be altered to almost any desired filament shape to achieve unusual luster effects, as well as altered physical and tactile properties. Because the surface tension of the melt leads to a rounded filament, melt temperature, melt viscosity, and

cooling rate must all be adjusted to achieve the desired filament cross section.

Spinneret holes of 200 – 400 μm can be used to produce nylon filament and staple yarns. The molten polymer extruded from the hole is pulled away by downstream rolls, reducing the diameter 5- to 50-fold. The diameter, or the mass per unit length, of the spun filament is determined by the rate at which polymer is metered through the spinneret hole and the rate at which it is pulled away. Small particles that pass through the filter leave weak spots in the filament, which may break in subsequent processing.

Nylons up to ca. 30 dtex/filament can be spun into air, but higher diameters require spinning into water or other liquids. Except for a few specialty uses, such large diameter filaments are generally made for nontextile applications. Turbid monofilaments are usually obtained when spinning into water, because of crystallization and surface corrosion. Clear filaments can be prepared by spinning nylon melts into cooled organic liquids such as carbon tetrachloride.

Unusual and useful filament structures can be prepared with specially constructed spinnerets [28]. Two melts are fed simultaneously to a spinneret hole, which results in a bicomponent filament that crimps spontaneously after drawing and finishing. Suitable melt pairs for this are nylon 66 and a 66 – copolyamide [29] or a copolyamide 612 [30]. Spinnerets with two concentric holes yield sheath-core filaments from two melts. Injection of an inert gas into the center hole causes a void to develop and results in a hollow filament cross section.

Grid spinning. Grid spinning was the original process for melt spinning of nylon.

Flake is gravity-fed from an overhead hopper and melted on a spiral coil or grid heated with diphenyl. An atmosphere of superheated steam is generally provided to control melt equilibration. In starting up a grid-spinning head, melted polymer dropping from the melting grid collects in a conical sump, flows into a pressure pump, and is fed to a metering pump where it is metered through the filter pack and spinneret. Because pump demand must always be smaller than the maximum melt capacity, the sump fills until the melt grid is immersed in the melt, thus automatically regulating melting via the free-grid surface. When the process is interrupted, the grid heat must be shut off, otherwise molten polymer will rise into the cooler zone and solidify to form a bridge that blocks the flake feed. The melting capacity of a grid-spinning unit with a grid diameter of 160 – 200 mm is ca. 30 – 60 g/min. Higher capacity can be achieved with larger grids. One melting grid can feed four or more spinnerets.

Extrusion Spinning. More modern spinning equipment uses melt extruders instead of grid units.

Extruders provide a shorter dwell time in the melt, better mixing, and better viscosity control. Their main advantage, however, is the large melt capacity, to ca. 1500 kg/d for a 150-mm-diameter screw.

Screws with length – diameter ratios of 20 – 30 are preferred to assure a more uniform melt temperature through the longer compression zone. An additional mixing zone connected to the compression zone improves homogeneity of the melt and permits increased throughput [31].

The melt is fed at constant pressure from the extruder through a jacket-heated transfer line to the spinning machine. One melt extruder can supply 30 – 40 individual spinning positions, each of which might spin eight or more individual thread lines. Use of a central filter for the melt, located between the extruder and the spinning block, is considered advantageous for some processes. This type of filtration is practical for nylon 6 but not as effective for nylon 66 because of the tendency of the latter to degrade and form gels in, and after, the filter.

Melted polymer must be fed to the individual spinnerets with the same average dwell time. Distribution piping is designed in cascade form to provide the same melt travel distance to each spinneret. In addition, dwell time differences arising from parabolic velocity distribution of melt inside the pipe must be balanced with static mixers ahead of each branch. Local or chronological nonuniformity of the melt can usually be detected first as dyeing differences in filament yarns.

Direct Spinning. Economic and quality advantages result by feeding continuously polymerized melt directly to the spinning machine. This is most easily accomplished with nylon 66, which produces only small amounts of low molecular mass cyclic amides. Direct spinning

becomes most attractive when a few products can be made in high volume and such products can be made with little change in overall throughput. Large transitional changes are to be avoided. In such systems, introducing additives into the melt downstream of the polymerization unit is also desirable. This requires additional expenditures for the preparation of melt concentrates, as well as for the melting, metering, and homogenization equipment required for injection.

As noted earlier, nylon 6 fibers can also be made by direct spinning, but the equilibrium mixture, containing substantial amounts of caprolactam and higher cyclic amides, must be dealt with. This is accomplished through *thin-film evacuation.*

The melt, prepared continuously in a polymerization tube, is passed to an evacuating assembly at 270 °C [32]. It is distributed through an annular slit onto a cylindrical wall, as a coherent film of melt. As the melt flows down the wall, volatile components (caprolactam and water) evolve at a pressure of ca. 10 Pa. At the bottom of the assembly, the evacuated nylon 6 melt is homogenized through a mixing stirrer and conveyed by a compression screw through the discharge and to the spinning machine.

1.5.2. Special Techniques and Products

Fine-Denier Nylon Filament Yarns. Most fine-denier filament yarns are used in wearing apparel and household upholstery. Products are in the region of 10 – 400 dtex total, with filament counts from 1 to > 100. Single filaments run from 1.5 to ca. 6 dtex (9 – 36 µm).

Spinnerets for fine-denier textile filaments are usually made of stainless steel, 40 – 70 mm in diameter and 10 – 15 mm thick. Because of the high viscosity of the melt, the spinneret hole initially has a large diameter (2 – 3 mm), called the counterbore, which tapers in a conical section to a smaller exit hole (200 – 400 µm) from which the melt is extruded.

With a windup speed of 600 – 1200 m/min, solidification in the quench (cooling) chimney is completed within ca. 50 cm of the spinneret. Cool air is blown at right angles across the filament path, and careful attention must be given to avoiding pulsation or turbulence in air flow.

Filaments leaving the quench chimney are moistened with a spinning finish (oils emulsified in water) to provide static protection and lubrication for further processing. Many filaments are combined after finish application to form the final, multifilament bundle. If the yarn is to be drawn in a separate step, it is normally passed through a steam tube to promote development of the proper crystalline structure. For coupled spinning and drawing, yarn can be forwarded from the feed roll, which pulls the filaments away from the spinneret, directly to a set of faster moving draw rolls and then to a package-winding unit. Textile yarns are commonly drawn three to four times the original spun length to develop the required tensile – elongation properties. Depending on the process and the end use, packages of ca. 1 – 20 kg are produced.

Economics of the spinning operation have been improved over the years by winding multiple packages on one winding unit, by winding larger packages for each thread line, and by operating the entire process at higher speed. Filament yarns are now prepared at spinning speeds of 5000 m/min, and useful fiber properties are now achieved in some cases without a separate drawing step [33]. Spinning, drawing, and texturing may also be combined in one continuous operation.

Coarse-Denier Nylon Filament Yarns. Coarse nylon yarns range from 400 to > 35 000 dtex total and from 6 to ca. 20 dtex per filament.

Rectangular spinnerets are commonly used, spinning several hundred holes per spinneret. In the production of high-strength nylon yarns (e.g., tire cord), draw ratios of 5 – 6 are used and drawing is commonly done in two stages, with heating, to develop maximum tenacity and low elongation. Tenacities of 8.0 cN/dtex and 15 – 17 % elongation are common for nylon 66 tire yarns. Package weights of 40 kg are common, and ends from several hundreds of these packages are combined and wound on a larger spool (beam) for shipment to the customer.

Nylon filament yarns for carpets and other floor coverings are usually sold in the range of 1000 – 3000 dtex total and 15 dtex per filament. Nylon for netting and ropes reach 35 000 dtex total, with 20 dtex per filament. These yarns are drawn four to six times their original length with

heat assists and are deposited in rope form in a can. Some of these are then stretched further in a hot water bath to develop maximum tenacity.

Wires and Bristles of Nylon. Coarser nylon filaments (0.05 – 5 mm) are generally made with a higher degree of polymerization. Copolyamides are often more suitable for fishing lines.

Several processing steps are frequently coupled in one continuous operation. Flake is melted in a single-screw extruder, and the melt is extruded through spinneret holes (1 – 10 mm in diameter). The coarse filaments are solidified in a water bath and drawn between rollers in air or hot water at a speed of 200 – 400 m/min. Thicker wires may be drawn through dies to set the draw point and round the cross section. To improve dimensional stability and stiffness, coarse filaments for bristles are heat-set in boiling water, either continuously or on reels or bobbins.

1.6. Uses

Fine-denier filament yarns, from 1 to 6 dtex per filament and up to about 400 dtex total, are used broadly in wearing apparel, such as ladies underwear, lingerie, stockings, pantyhose, and outerwear; in shirting, elastic outer clothing, and recreational clothing; and in home upholstery and automotive decorative coverings. Heavy-denier filament yarns, 6 – 20 dtex per filament and up to 3000 dtex total, are used in carpets and other floor coverings, belt fabrics, tire cord, netting, and ropes. Nylon staple fibers, ranging from 1.0 to 15 dtex per filament, are used directly or blended with cotton, felt, and other synthetics for apparel, floor covering, and industrial uses. Monofilament nylons, 20 to > 1000 dtex per filament, are used in items such as fishing lines, luggage, paintbrush bristles, and cordage.

1.7. Economic Aspects, Manufacturers, and Trade Names

Some 3.9×10^6 t of nylon fiber was produced worldwide in 1988 (see Table 6), with a value of over \$ 11×10^9 [302]. Over 98 % of the total is either nylon 6 or nylon 66. Whereas the fraction of nylon 6 was only 9 % in 1953, vs. 91 % for nylon 66, worldwide shipments of the two are now about equal. Installed worldwide capacity, approaches 4×10^6 t. In 1985, the geographic distribution of production was 36 % North America, 23 % Western Europe, 17 % Asia (including Japan and Taiwan), and 24 % all other; sales by end use were 38 % for apparel and home furnishings, 34 % for carpets (mostly face fibers), and 28 % for industrial uses (truck tires, conveyor belting, etc.); an additional 1.0×10^6 t of nylon resin was produced for nonfiber applications. Major producers of nylon fibers are listed in Table 7 along with types and representative trade names.

Table 6. World production of nylon fibers∗

Year	Production, t	Production, %∗∗
1940	5 400	95
1950	62 000	90
1960	410 000	58
1970	1 908 000	38
1980	3 151 000	30
1985	3 396 000	27
1988	3 900 000	

∗ Data compiled from *Textile Organon.*

2. Polyester Fibers

History. The first spinnable high molecular mass polyesters were prepared by W. H. Carothers and co-workers in the laboratories of E. I. du Pont de Nemours & Co. around 1930 [34]. Dicarboxylic acids in use then were sebacic acid, hexadecanedicarboxylic acid, and others; some diols used were ethylene glycol and propylene glycol. The discovery that hardened spun strands could be drawn to several times their original length and, thereby strengthened, was made with these polyesters [35]. However, their melting points were ca. 75 °C, too low for practical application. For this reason, Carothers turned his attention to the more promising polyamides [36].

In the late 1930s, investigations showed that terephthalic acid and other aromatic acids could yield useful polyamides. Therefore, polyesters containing terephthalic acid as the dicarboxylic acid were studied at several locations [37]. Poly(ethylene terephthalate) was discovered in the laboratories of Calico Printers Association. Beginning in 1940, Whinfield and Dickson devoted themselves mainly to poly(ethylene terephthalate) [38], [39], while Schlack was working on poly(tetramethylene terephthalate) [40].

In 1947, ICI and Du Pont acquired patent rights for Great Britain and the United States, respectively, and initiated the commercial development of polyester fibers [37]. In the early 1960s, ICI licensed its technology worldwide to some large fiber producers whose own developments led to today's mass production. Thus, poly(ethylene terephthalate) has gradually become the most important fiber polymer [41].

According to DIN definition 60 001, fibers are designated polyester if the polymer chain contains at least 85 % of an ester of a diol and terephthalic acid. Poly(ethylene terephthalate) [*25038-59-9*] (PETP), poly(oxy-1,2-ethanediyloxycarbonyl-1,4-phenylenecarbonyl), is a polyester with terephthalic acid [*100-21-0*] as the dicarboxylic acid and ethylene glycol as the diol ($n = 80 - 150$):

For a detailed description of the chemistry, raw materials, production, and analysis of polyesters, see → Polyesters. The following discussion contains information pertinent to an understanding of the production and properties of these fibers. Section 2.1 covers aspects of production common to all types of PETP fibers; specific information can be found under the individual fibers (Sections 2.2 and 2.3).

2.1. Production

2.1.1. Starting Materials and Polymer

Ethylene Glycol [*107-21-1*]. Ethylene glycol is produced commercially by the reaction of ethylene oxide with water, which in turn is obtained by the oxidation of ethylene (→ Ethylene Glycol; → Ethylene). Prerequisites for smooth polycondensation to poly (ethylene terephthalate) and for the desired polymer properties are extreme purity of ethylene glycol and other raw materials and the absence of water.

Dimethyl Terephthalate [*120-61-6*] (**DMT**). Until the end of the 1960s, economical production of terephthalic acid in the purity required for fibers was difficult. For that reason, the more easily available dimethyl ester of terephthalic acid was generally chosen as the starting component for PETP (→ Terephthalic Acid, Dimethyl Terephthalate, and Isophthalic Acid).

This material is produced commercially primarily by the *Witten process* (identical to the Imhausen or Katzschmann process [42]).

p-Xylene [*106-42-3*] is subjected to a two-step, liquid-phase oxidation in air. The *p*-toluic acid so produced is esterified with methanol to the methyl ester of *p*-toluic acid, which is then esterified with methanol to DMT.

Terephthalic Acid [*100-21-0*] (**TPA**) (→ Terephthalic Acid, Dimethyl Terephthalate, and Isophthalic Acid).

Since the early 1970s, extra pure terephthalic acid of fiber quality has been produced commercially primarily by the *Amoco process* [43].

Inhibition of the oxidation of the second methyl group of *p*-xylene is suppressed with the aid of added bromine-containing promoters as

cocatalysts. As with DMT, the oxidation takes place in air and produces raw terephthalic acid, which is dissolved at high temperature under pressure in water, hydrated, and thus purified.

Polymer. The polymer is prepared in two steps:

1) Transesterification of dimethyl terephthalate (**1**) with ethylene glycol to bisglycol terephthalate (**2**) (continuous or batchwise) or direct esterification of terephthalic acid.
2) Polycondensation (continuous or batchwise) to give poly(ethylene terephthalate) (**3**).

The batch process is preferred for special polymer types, particularly for small amounts of polymer. The continuous process is used for standard polymer types in large volume, especially if spinning immediately follows polycondensation.

Poly(ethylene terephthalate) from Dimethyl Terephthalate. Commercial transesterification of dimethyl terephthalate with subsequent polycondensation was initially carried out batchwise.

Batchwise Process. First, DMT is esterified as quantitatively as sible with an excess of ethylene glycol (molar ratio range of DMT to ethylene glycol 1 : 2.5 to 1 : 4.5) between 150 and 180 °C. Catalysts are primarily zinc, calcium, and manganese acetates. Bisglycol terephthalate, as well as higher homologues, are formed. Excess glycol is distilled at temperatures up to 250 °C.

Polycondensation is carried out at higher temperatures, up to ca. 285 °C, under vacuum. In this step, the catalysts are primarily antimony trioxide or oxides of similar amphoteric metals. Phosphorus compounds are added as stabilizers to inactivate the transesterification catalyst.

Other additives, e.g., titanium dioxide for delustering or carbon black for black coloration, can be added to the melt prior to polycondensation. Once polycondensation is complete, the condensate is forced out of the vessel with nitrogen and quenched in water. The melt, which is thus solidified largely in the amorphous state, can then be formed into chips.

Continuous Process. Continuous transesterification and polycondensation occur in several, mostly horizontal, reactors in a manner similar to the batchwise process.

As the polyester melt is formed during condensation, care is taken to keep its layer thickness small and its surface correspondingly large. This is necessary because diffusion of excess glycol determines the rate of polycondensation. Discharge from the last reactor occurs by means of an extruder or a pump. The polyester melt is then either passed to the spinning units and spun immediately or chilled in water and cut into chips. Continuous processing units are generally quite large, with throughputs of up to 100 t/d and average holdup times of the material in the unit of 5 – 10 h.

Poly(ethylene terephthalate) from Terephthalic Acid. Since highly purified, fiber-grade terephthalic acid has become available at low cost, it is increasingly being esterified directly with ethylene glycol (molar ratio of terephthalic acid to ethylene glycol 1 : 1.1 to 1 : 1.5).

The reaction occurs at about 260 °C under pressure and generally requires no catalyst. Lower linear oligomers are formed. After the glycol has been distilled, polycondensation follows. Its course is similar to that with DMT as the starting product. A polycondensation catalyst is also required.

The economic advantages of this route are that circulation of methanol is eliminated, substantially less excess glycol is necessary, and above all, the amount (in grams) of starting material required is less by ca. 14 % because of the lower molecular mass of TPA vs. DMT. However, direct esterification results in somewhat more diethylene glycol byproduct. This process is used in continuously operating modern plants.

Poly(ethylene terephthalate) with Very High Molecular Mass. Industrial end uses require very high molecular masses (corresponding to very high average lengths of molecules) to attain the necessary tenacity and modulus. Because removal of excess glycol in polycondensation is rate determining, reducing the thickness of the melt layer as the reaction progresses would be appropriate. However, due to the melt viscosity increase during polycondensation, this becomes more and more difficult. Holdup time at high melt temperature is thus increased, which produces thermal degradation in parallel with polymerization. Polymer whiteness thus deteriorates, and COOH end groups are formed in undesirable concentrations in addition to the OH end groups. To get around these problems, PETP of very high molecular mass is now generally produced by *postcondensation in the solid phase* (solid condensation).

Granulate PETP, produced by melt condensation, is dried and exposed to heat either batchwise in vacuum or continuously under an anhydrous gaseous protective blanket free of oxygen (generally nitrogen) at temperatures up to ca. 250 °C (i.e., somewhat below the melting point). A lamellar structure with noncrystalline regions and voids forms (→ Fibers, 2. Structure). Polycondensation occurs in parallel with recrystallization and additional crystallization. The glycol – water mixture produced diffuses through the noncrystalline regions and mainly through the interlamellar voids that are being formed. The result, in addition to acceptable polymer color, is primarily the desired low concentration of COOH end groups. Once the desired average molecular mass has been attained, the granulate is chilled and packaged. Alternatively, it can be melted directly with the exclusion of water and sent to the spinning units.

2.1.2. Spinning

The melting point of poly(ethylene terephthalate) (265 °C) is clearly below the decomposition temperature of the melt; therefore, PETP can be melt-spun (see also → Fibers, 3. General Production Technology, Chap. 3.1.). During melt spinning, a molecular orientation is created in the filaments by the drawdown tension; this orientation is frozen during cooling. Here, PETP exhibits a special characteristic which distinguishes it from other commercial melt-spinnable polymers: because of its relatively high glass transition temperature (70 °C), the spun material solidifies completely in the spinning shaft to form a stable, supercooled melt with molecular orientation more or less in the yarn direction [37]. This orientation, measured by birefringence, is proportional to the tensile stress along the path of the yarn at the time and place of solidification, [44], [45].

As filaments solidify, they also attain their final speed (winding speed) and thus their final linear density (as-spun fineness). Where the solidification point lies along the path of the as-spun yarn, depends on spinning conditions; distances between 20 and 150 cm from the spinneret have been reported [45].

Because of the relatively low tendency of PETP to crystallize at room temperature, the as-spun yarn is amorphous as long as drawdown tensions are not too great. Stress-induced crystallization occurs only at higher tensile stress as a result of spinning speeds above ca. 3000 – 4000 m/min or of very intense air quench; this crystallinity also is frozen into the yarn. Under these processing conditions, the as-spun yarn is partially crystalline [46], [47].

At very high spinning speeds (at about 8000 m/min), the crystallinity of the as-spun yarn can be as high as 50 % [48], [49], and the distribution of directions of the crystallites becomes even more narrow. At the same time, the layered structure of crystalline order, which resembles that of PETP spun slowly and then drawn, is slowly transformed into a more fibrillar structure of larger ordered regions. Despite the high orientation of the crystalline fractions, the total orientation again decreases somewhat; therefore, orientation of the amorphous material between the fibrils is assumed to decrease [50].

At spinning speeds > 4000 m/min, an additional sheath-core orientation occurs in the filaments [48]. This effect can cause the orientation in the sheath, measured by birefringence, to be almost twice as great as in the filament core [51], [52]. Correspondingly, the sheath of the filaments is also more highly crystalline. These differences remain during further processing of the as-spun yarn and can lead to nonuniformities in dyeing if they are not controlled in the process [53].

As mentioned, the orientation and even the crystallinity of filaments depend on spinning conditions and increase with increasing spinning speed, stronger air quench, and higher molecular mass. Both characteristics decrease with increasing spinning temperature, with higher mass transport, and thus with greater as-spun linear density. If the spinning speed is increased and the fineness is held constant by a proportional increase in mass transport, the effect of spinning speed predominates. The orientation and even the crystallinity increase [45][46][47]. The diameter of the spinneret holes, hence the spin–draw ratio, has relatively little effect on the final spin orientation and crystallinity except when spinning speeds are $\geq$5000 m/min [50].

Orientation and crystallinity of the filaments are characteristics of the as-spun yarn that must be considered in further processing because of their effect on the properties of the end product. Both factors are held as constant as possible with respect to time and between the spinning units.

Spinning Process. As described in Section 2.1, PETP is produced either continuously or batchwise. In the continuous process, the spinning and polymerization units can be connected. Thus, freshly condensed melt flows directly to the spinning units. Because the economic advantages of direct spinning are obvious, its use for high-volume end products, e.g., for staple fibers and standard filament yarns, which are always made by the same process, is increasing constantly [84].

The PETP granulate that is delivered to a spinning plant is first stored in silos. The granulate must be dried immediately before melting because even the smallest amount of water in the polymer causes hydrolytic degradation of the melt. Residual water content < 0.01 % is desirable.

Drying is carried out mostly in continuous shaft dryers. The granulate moves slowly downward, while a hot, often predried, countercurrent air stream blows over it. Since amorphous PETP granulate tends to become sticky during heating, a crystallizer in which the chips are slightly crystallized, at least on the surface, often precedes the dryer [55]. Many dryer designs are known, with throughputs amounting to several tons per hour. For some products, drying the PETP granulate in a vacuum is better, for example, in batches in large tumble dryers.

From the dryer, the granulate reaches the melt extruder, which transports the melt to one or more spinning machines. Because of thermal degradation of the melt, maintaining equal holdup times in the hot lines between the extruder and the attached spinning units is important; the temperature of these lines must also be the same. Only then can the uniformity of the as-spun yarn and the end products be assured.

Spinning units differ considerably in construction and processing data, depending on the end product. The same is true for the method of cooling, finishing, drawing down, and collecting the as-spun yarn [37]. Common operational winding speed ranges from ca. 500 m/min for industrial yarns to 6500 m/min for filament yarns spun at the highest speed. Thick filaments, e.g., monofilaments, are spun at a much lower speed. Common to all is the spinning temperature, which is 270–310 °C. For details, see Section 2.3.

2.1.3. Drawing

The glass transition temperature of PETP is ca. 70 °C, which is somewhat above room temperature. Therefore, when PETP yarn spun at relatively low speed is elongated slowly, cold drawing occurs with a draw point [54]. From the linear densities on both sides of the draw point or from the length of the plateau of the stress–strain diagram (see Section 2.2.2), a "natural draw ratio" can be specified. This ratio depends on the orientation of the as-spun yarn, which already represents a part of the total orientation [56]. The product of the orienting spin–draw and the natural draw ratio is constant to a first approximation and is equal to ca. 6–7 [57].

In commercial practice, as-spun PETP yarn is always drawn at a temperature $\geq$ 80 °C. Because of the added work of drawing, the real yarn temperature in the draw zone is frequently higher than the external temperature, depending on the drawing arrangement.

During drawing [44], the molecular network of the as-spun yarn is oriented further. The increasing parallelism of the molecular chains initiates PETP crystallization. With further drawing, the crystalline regions and the amorphous

areas between them become more and more oriented [58]. Orientation, crystallinity, and strength of the drawn yarn increase with increasing draw ratio, whereas break elongation decreases [59]. This is illustrated by the stress–strain diagrams of yarns drawn differently (Fig. 1).

Figure 1. Stress – strain curves of two drawn PETP yarns
—— Draw ratio 1 : 1.52; – – – – Draw ratio 1 : 1.83

In addition, the product of orienting spin-draw and draw ratio is approximately constant for the maximum possible draw ratio and for drawing to a given break elongation [57]. Thus, PETP yarn spun at higher speeds needs to be drawn less to attain a given break elongation. However, this affects the structure of the drawn material [53], [57], [60]. Because less energy is added during drawing, the crystallinity is somewhat lower, and both the total orientation, as measured by birefringence, and the tenacity of the yarn are reduced [61]. These relations begin to change at spinning speeds of ca. 5000 m/min. Then the as-spun yarn is so highly crystalline that the ordered regions are no longer loosened during drawing but orient themselves as far as possible as a whole along the fiber axis. The crystallinity again increases [48].

The more the drawing temperature exceeds the glass transition temperature the more easily can PETP be drawn [44]. Drawing tension drops if drawing temperature is increased and also if the glass transition temperature is decreased, either by water absorption by the as-spun yarn [37] or by modifications of the polymer. However, drawing temperature must not be set too high, for then the purely plastic and nonorienting elongation becomes too large a percentage of the total draw.

The draw ratio would have to be set very high to achieve high strength. The yarn in the draw zone would then no longer be able to absorb stresses and would break. As with other polymers, two-stage drawing is necessary; the predrawn yarn enters a second draw zone where it is then capable of withstanding the drawing tension.

Drawing Process. In industrial practice, PETP as-spun yarn is almost always drawn continuously between two godets or sets of rolls, whose speeds determine the draw ratio [54]. In so doing, the required draw temperature is imparted to the yarn by heaters or heated rolls [37]. Keeping the draw point stationary is important; otherwise the drawn product will contain differentially drawn areas, which produce defects, particularly nonuniform dye uptake. Details of each drawing arrangement are dictated by the product to be drawn (see also → Fibers, 3. General Production Technology, Chap. 2.2.).

2.1.4. Aftertreatment

Thermal Aftertreatment. At room temperature, oriented and noncrystallized segments of the PETP molecular chains in a drawn thread-like structure are frozen and immobile; the entire structure is not in equilibrium. When the yarn is heated beyond the glass transition temperature, the amorphous chain segments begin to move so as to achieve an entropically more favorable, less oriented position, to the extent permitted by their restraints in the crystalline regions. These regions also lose orientation and, as an overall result, the yarn shrinks. The extent of shrinkage depends on the orientation and crystallinity of the drawn structure; it increases with increasing temperature and, initially, also with the duration of heat treatment [44], [59], [62]. Any plasticizers, e.g., water, that have diffused into the structure favor shrinkage.

The thermal instability of drawn PETP yarn structures would be quite troublesome during further processing and in textile end products. Therefore, it is often reduced during fiber and yarn manufacture by a thermal aftertreatment called *heat-setting* (see also → Fibers, 3. General Production Technology, Chap. 2.4.) [37], [63].

Structures that are allowed to shrink without restraint between 110 and 180 °C are thermally stable below the setting temperature. In this process, orientation decreases markedly, which

manifests itself on the stress – strain curve as a saddle with a yield stress of ca. 1 cN/dtex (Fig. 2). If the product, which has been heat-set without restraint, is loaded to this yield stress saddle, it is permanently deformed. In general, normal textile applications rarely reach this amount of loading.

Figure 2. Stress – strain curves of drawn PETP yarn, subsequently allowed to shrink freely
– – – – Drawn yarn; —— Drawn and allowed to shrink freely for 5 min in steam

During unrestrained heat-setting, crystallinity increases considerably, primarily favoring the ordered regions already present. Degrees of crystallinity up to 50 % have been reported. The amorphous fraction is correspondingly reduced, but the chain segments are disoriented in response to shrinkage. With increasing crystallinity, maximum dye uptake (i.e., the saturation concentration) decreases but dye diffusion becomes much easier as the amorphous chain segments disorient. In this way, dyeability reaches a minimum at heat-setting temperatures of 150 – 180 °C [59], [62], [64].

If heat-setting takes place at constant length without any shrinkage, the effects are intensified with temperature and duration of heat-setting. Crystallinity also increases but less so than during unrestrained heat-setting. The PETP products are not completely stable thermally but will retain some residual shrinkage [59], [63]. Therefore, the temperature at which this type of heat-setting is carried out is frequently very high, e.g., 220 °C. Cooling the material under tension after it leaves the heat-setting zone is important to prevent any shrinkage. Heat-setting at constant length decreases extensibility and increases strength.

Hot postdrawing of a previously drawn yarn represents heat-setting with negative shrinkage. Crystallinity and orientation increase markedly, and the initial slope of the stress – strain curve of the yarn and the tenacity increase. The extent of changes in shrinkability depends on processing conditions.

In practice, a middle course is often adopted, i.e., heat-setting while constant shrinkage is allowed [63]. This increases crystallinity and somewhat reduces orientation. The increase in extensibility of the material approximately corresponds to the shrinkage permitted; at the same time, a slight saddle is formed on the stress – strain curve. The residual shrinkage of material heat-set in this way is smaller by about the amount of shrinkage permitted during setting. The many processing parameters, such as draw ratio, heat-setting temperature, and shrinkage allowed during setting, permit matching the properties of the PETP product quite closely to the requirements of each end use.

Heat-setting does more than prevent thermal instability. The structural rearrangements it induces make prior changes in shape impressed on the yarn permanent [37]. This feature is used widely in producing and processing fiber products, e.g., in ironing or pleating when creases are to be set hot. However, in producing the fibrous structure and in further heat-setting, care must be taken to chose conditions which will assure that any subsequent heat-setting will still be effective. "Deadening" a fiber (or a textile structure formed from it), so that it can no longer be heat-set, should not be done.

During setting, primarily the orientation of the amorphous parts changes; however, growing crystalline regions also disorient if any shrinkage has been permitted. This leads to a corresponding change in the superstructure of the PETP fiber. In general, the layered structure becomes more pronounced. The orientation angle of the crystalline layers with respect to the fiber axis increases [59].

Structural rearrangements during heat-setting and the resultant changes in textile properties depend in a complicated way on the structure and prior history of the PETP yarn and on the conditions of the heat-setting process. Therefore, formulating general, quantitative relationships is impossible. These depend on the given heat-setting process, which differs from product to product. All setting processes are included in the manufacturing process immediately after drawing or deformation.

Deformation. Melt-spun fibers including PETP are generally flat and, in this condition, unsuitable for many applications [37]. Hence, all staple fibers and tows must be matched to natural fibers by *crimping*.(→ Fibers, 3. General Production Technology, Chap. 2.3.) PETP filament yarns for apparel are *textured* (→ Fibers, 3. General Production Technology, Chap. 3.3.) on a large scale. The processes and installations used in both cases are quite similar for all manmade fibers. The deformations produced are frequently heat-set, either without tension (staple fibers heat-set without restraint) or with tension (texturing), depending on the product. The features specific to PETP are product-related and, where necessary, are described in Chapter 3.

2.1.5. Dyeing of Poly(ethylene terephthalate) Fiber Products

Dyeing of textiles and dyeing technology in general are discussed under → Textile Dyeing.

As a result of polycondensation and subsequent degradation, PETP contains OH and COOH end groups. Neither is suitable for bonding ionic dyes. Therefore, PETP is dyed with disperse dyes unless it has been modified to contain ionic end groups (→ Disperse Dyes). These dyes are available in powder or liquid form. They are only slightly soluble in water and are, therefore, used as aqueous dispersions in the dye bath or even as foam. Dye preparations necessarily contain dispersants.

Migration of dyes into the fiber is controlled by the laws of diffusion [65]. The parameter determining the rate of migration is thus the diffusion constant D, which depends on the size and structure of the dye molecule. The saturation concentration c_∞, reached at very long dyeing times, is the second parameter required to describe the kinetics of dyeing.

Investigations have shown that D is affected substantially by the orientation of the molecular segments in the noncrystalline region of the fiber. With increasing orientation, molecular mobility decreases, and the glass transition temperature T_g, a measure of mobility, increases. Beginning at ca. 68 °C in an isotropic, amorphous PETP, T_g can reach 100 °C in a highly oriented, partially crystalline fiber [66], [67].

The diffusion constant is also affected by the ordering of the molecules, though to a much lesser degree. This becomes evident if the temperature of heat treatment prior to dyeing exceeds 180 °C. Above this temperature, the noncrystalline regions (layers between crystalline layers) are loosened, which restores the mobility of the molecular segments in these regions; parts of molecules that up to then had been extended can coil up or even refold, which leads to a growth in crystalline regions transverse to the molecular axis and to an "emptying" of the noncrystalline regions. Material that has been spun at high speed and then drawn behaves similarly (see Section 2.3.2) [53]. However, such ordered states in the noncrystalline regions of the fiber are first of all key to controlling the saturation concentration c_∞.

The fiber can take up dye to any significant degree only at temperatures above T_g. At these temperatures, the polymer is present as a highly viscous liquid in which the mobility of molecular segments in the noncrystalline regions is restricted. The saturation concentration evidently depends on the accessible free volume in the noncrystalline regions and in voids. It is also certainly affected by the structure of the interfaces of these volumes. A quantitative description is not yet possible.

Thus, with reference to fiber structure, the diffusion constant D is the most important orientation-dependent kinetic parameter of dye migration through the "liquid" polymer regions. The saturation concentration is determined by the states of order of the supercrystalline structure (small-angle X-ray structure). However, practical dyeing behavior is essentially determined by the diffusion constant.

Poly(ethylene terephthalate) fibers can be dyed to deep shades without using auxiliary chemicals only at temperatures ca. 50 °C above the glass transition temperature. Such dyeing is carried out in aqueous media under pressure in a closed vessel and is called high-temperature (HT) dyeing. High-temperature dyeing of textiles made of 100 % PETP or blends of PETP with cotton or other cellulosic fibers presents no problems. Any wool in the blend, however, is damaged.

Carriers are used for open dyeing in boiling water, especially of blends of PETP and wool. These chemicals are swelling agents, i.e.,

poor solvents, for the polyester fiber. They temporarily loosen intermolecular bonds in the fiber and thus increase the mobility of molecular segments. In other words, they lower the glass transition temperature. The problems connected with cleanup of wastewater are a disadvantage.

Therefore, PETP fibers have been developed that can be dyed to deep shades in boiling water without carrier (see Polymer, Section 2.2.1) [68]. These fibers contain block comonomers, generally polyglycols, and meet all requirements of the apparel and home furnishings trades. However, minor losses in light- and washfastness of the dyeings compared to unmodified PETP are unavoidable.

Ionic dyeing for differential dyeing requires appropriate ionic end groups in the molecule. Sodium salts of 5-sulfoisophthalic acid dimethyl ester [*138-25-0*] and 5-sulfoisophthalic acid [*22326-31-4*] have been used; they can be added during transesterification of DMT or during direct esterification of TPA [69]. Fibers can be dyed with cationic dyes without difficulty, but the dyeings are much less lightfast.
